Abstract

In Balkh province as well as in the most parts of Afghanistan, fluoride contamination along with other water quality concern parameters can be an issue for current drinking water supply systems using groundwater and potentially affect the health of inhabitants.

Therefore, the study carried out analyzing physical and chemical parameters integrating data sets from various projects collected for UNICEF (collected and tested water samples to identify fluoride and arsenic contamination in Balkh province), ECHO (collected and tested water samples to identify water point qualitative and quantitative functionality) and DACAAR GMWs network and WASH projects. The purpose of this study is to identify the water qualitative characteristics and hydro chemical process influencing the fluoride concentration of water point (WPs) sources (groundwater and surface water) of Balkh, Nahri Shahi, Dawlatabad, Chahar Bolak, Chimtal, Dehdadi, Khulm, Kaldar, Marmul, Charkint and Zari districts of Balkh province. For this purpose, 380 water samples (WSs) from different locations covering tube wells (TW), dug wells (DW), springs, stand posts (SP), streams and rivers were collected and analyzed for physical and chemical parameters according to the DACAAR water quality laboratory procedures and guideline.

The concentration of fluoride in the water samples ranged between 0.02 mg/l and 12.9 mg/l and the results revealed that 38% of tested water samples exceeded the National Drinking Water Quality Standard (DWQS) of 1.5 mg/l. Finding high concentration in the water sources in some localities such as Nahri Shahi, Dawlatabad, Chahar Bolak, Chimtal, Dehdadi, Khulm, Kaldar and Shortipa districts of Balkh province is great concern and some people did show affects from high levels of fluoride.

The result of this study also revealed other water quality concern parameters such as Electrical Conductivity/salinity (EC), Nitrate, Boron, Sodium, Chloride, Magnesium and Calcium concentrations are considerably higher than NDWQ standard which can potentially affect the health of inhabitants of Balkh province.

Key words: *Fluoride contamination along with other water quality concern elements, major ions chemistry, hydro-chemical process and correlations analysis*

Acknowledgments

I would like to thank DACAAR personnel for the support, constructive suggestion, and valuable recommendations and for analyzing of water samples groups. The kindness and cooperation of all of our staffs and co-helpers is greatly appreciated.

I would not be able to finish this scientific report without continual support of the following staffs:

- Leendert Vijselaar, Coordinator WASH Closter Co-Lead of DACAAR hard work for revising and correction of this report
- Ahmad Jawid, WASH Hydro geologist recorded and managed water quality and quantity data and provided charts, graphs and tables.
- Khalil Rahman, Laboratory Supervisor supervised physical and chemical analysis of water samples
- Abdul Ahmad, Nasratullah and Qudratullah lab technician were analyzed bacteriological, physical and chemical of water samples.
- Assadullah, field supervisor for GMWs data collection in north, North West and north east of Afghanistan

1. Introduction

In Balkh province, the surface water is scarce due to the unequal and uneven distribution of precipitation. Therefore the groundwater is the most important source of water for the inhabitants in the rural and urban areas of Balkh province as well as for the whole of Afghanistan. It is hidden resources, it is a finite and it is also extremely vulnerable and sensitive to the geological setting, over-exploitation and contamination. It is critical to investigate qualitative and quantitative status of groundwater for efficient and effective use, development and protection.

Fluorine is halogen a high electronegative and reactive element and does not occur in a free form in nature, and it is present as fluoride ions in drinking water. It occurs as fluoride ions naturally in soil and water due to chemical weathering of some fluoride containing minerals (Totsche, 2000). Fluoride in small amounts is an essential component for normal mineralization of bones and formation of dental enamel (Bel and Ludwig 1970).

The fluoride concentrations in drinking water has beneficial and can have detrimental effects on human health. Low concentrations of fluoride in drinking water are hygienically desirable, to strengthen teeth, however high concentration of fluoride in drinking water is associated with dental fluorosis (yellowish or brownish staining or mottling of the enamel), skeletal fluorosis and crippling skeletal fluorosis. The high fluoride content of water ($> 1.5 \text{ mg/ l}$) is toxic for humans, animals and plants.

The WHO permissible limit of fluoride in drinking water is 1.5 mg/l (WHO 2004), the bureau of Indian standards (BIS, 1990) has suggested the permissible limit of fluoride in drinking water to be 1 mg/l , however the National DWQSiS 1.5 mg/l .

2. Objectives

2.1 Overall objective

Overall objective of this report is to provide a detailed picture of fluoride spatial distribution and concentration, along with other water quality concern parameters and their impact on human health in the rural areas of Balkh province.

2.2 Specific objective

The following are the specific objectives of this study:

- Evaluate tested water samples quality (physical and chemical) parameters of concern
- Map and visualize spatial distribution levels of fluoride along with other water quality parameters that interact with fluoride
- Identify the areas where the fluoride and other water quality elements are higher than national DWQS and potentially affect the health of inhabitants.
- Identify aquifers hydro-chemical processes and trends which influence fluoride concentration.

3. Rational of the study

Groundwater is the major source for water and especially for safe water supply in Afghanistan. It does not, however, have a large potential for development as it is a finite and hidden resource. The source should be studied to understand its qualitative and quantitative status for efficient and affective using, development and protection. The rational of this study are:

- To provide a detailed picture of drinking water points quantitative functionality and impact of fluoride concentration and interaction with other elements in drinking water supplies and the links between water use and health outcome in connection to fluoride.
- Highlights water related qualitative problems to support decision makers and policy makers for improvement of policies strategic plan and regulation regarding groundwater resources usage, development, protection and sustainability.
- Enhance technical capacity and institutional capability to implement water supply project according to the National DWQS.

4. General information about Fluoride.

4.1. Chemical description

- Fluorine is the lightest member of the halogen group and is one of the most reactive of all chemical elements.
- Fluorine is not found as fluorine in the environment, but it is always present in combined state as fluoride.
- Fluorine is the most electronegative of all the elements and has a strong tendency to acquire a negative charge in solution from fluoride ions.
- Fluoride is present about 0.06 – 0.09 per cent of the earth's crust.
- Fluoride above an optimal level (1.5 mg/L) is becoming progressively more toxic.
- Fluoride ions have the same charge and nearly the same radius as hydroxide ions and may replace each other's in mineral structure (Hem, 1985).
- Low concentrations of fluoride in drinking water are hygienically desirable, to strengthen teeth, high concentration of fluoride in water is toxic for animals and plants.

4.2 Environmental Occurrence.

- a) Granite (igneous rock) with pegmatite layer, gneiss and schist (metamorphic rocks) rocks are the major geological formation that contributes to fluoride concentration in groundwater. The minerals composition of granite is composed of quartz, feldspar and fluorite, whereas gneiss and schist are composed of quartz, k-feldspar hornblende, biotitic and fluorite. The fluoride-bearing minerals with interaction of water provide a significant fluoride level in groundwater.
- b) Granite and gneiss rocks are highly weathered which facilitate release of fluoride from minerals into groundwater.
- c) Fluoride is commonly associated with volcanic activity and fumarolic gases.
- d) Thermal waters with high pH, are also rich in fluoride (Edmunds and Smedley 1996)
- e) Granite rock polishing industries are source of fluoride concentration in groundwater
- f) Due to dust, industrial production of phosphate fertilizers, coal ash from the burning of coal and volcanic activities, fluorides are widely distributed in the atmosphere.

4.3. Fluoride Distribution in Water.

Fluoride is found in all natural water sources. Sea water typically contains about 1 mg/L, river and lake water have less than 0.5 mg/L, however in groundwater low or high concentration of fluoride can occur, depending on the nature of the rocks and occurrence of fluoride-bearing minerals.

The fluoride concentrations in water is limited because solubility of fluorite minerals (CaF_2), so that in the presence of 40 mg/L calcium should be limited to 3.1 mg/L (Hen, 1989). It is the absence of calcium in solution which allow higher concentrations to be stable (Edmunds and Smedley, 1996)

High fluoride concentrations may also increase in groundwater from calcium-poor aquifer and in areas where fluoride-bearing minerals are common. Fluoride concentration may also increase in groundwater in which cat ion exchange of sodium for calcium occurs (Edmunds and Smedley)

4.4. Exposure

Due to dust, industrial production of phosphates fertilizers, coal ash from the burning of coal and volcanic activity, fluoride is distributed in the atmosphere. The air is responsible for only a small fraction of total fluoride exposure (USNRC, 1993).

In non-industrial areas, the fluoride concentration in air is quite low (0.05-1.9 μm^3 fluoride)(Murray. 1988). In areas where fluoride-containing coal is burned or phosphate fertilizers are produced and used, the fluoride concentration in air is elevated.

A number of products administered to, or used by children to reduce dental decay contain fluoride. This includes toothpaste (1.0-1.5 g/kg fluoride), fluoride solutions and gels for topical treatment (0.25-24 g/kg fluoride) and fluoride tablets (0.25, 0.50 or 1mg fluoride per tablet) among others. These products contribute to total fluoride exposure, albeit in different degrees.

Vegetables and fruits normally have low levels of fluoride and thus typically contribute little to exposure. However, higher levels of fluoride have been found in barley and rice (about 2 mg/kg) and taro, yams and cassava been found to contain relatively high fluoride levels.

Alkalinity, evaporation and high bicarbonate content of groundwater are the factors contributing to the dissolution of fluoride rich minerals in weathering rocks.

4.5. Problem due to excess fluoride

Low concentrations of fluoride in drinking water are hygienically desirable, to strengthen teeth, however, high fluoride content of water ($> 1.5 \text{ mg/l}$) is toxic for human, animals and plants.

Long term use of fluoride content drinking water at concentration above 1.5 mg/l can result in dental fluorosis, value above 4 mg/l can result in skeletal fluorosis and above 10 mg/l causes crippling fluorosis [4]. The impact of using high fluoride content on human health is shown in table 1. The NDWQS for fluoride is recommended at 1.5 mg/l.

Table 1: Impact of fluoride on human health due to excess fluoride

Concentrations of fluoride in drinking water (mg/l)	Impact on human health
0 - 0.5	Dental caries, promotes dental health resulting in health teeth
0.5 - 1.5	Prevent tooth decay
1.5 - 4	Dental fluorosis
4- 10	Dental, skeletal and crippling fluorosis
> 10	Pain in back and neck bone

Fig.1, .2, 3 and 4 show the impact of fluoride on human health due to excess fluoride.

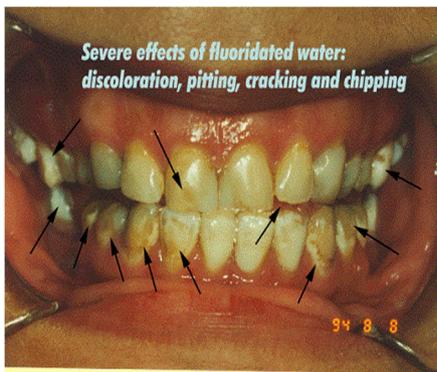

Figure 1 Fluoride effect on teeth

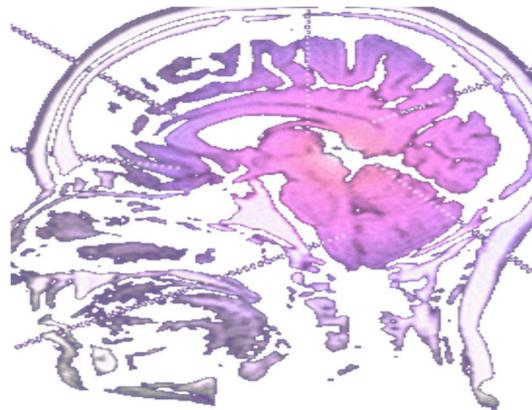

Figure 2 Fluoride effect on brain

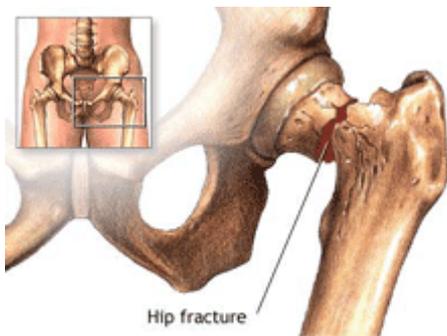

Figure 3 Bone fluorosis

Figure 4 Arthritis

5. Factors affecting the natural fluoride concentrations

5.1 Geology

During weathering and circulation of water in rocks and soils, fluoride can be leached out and dissolved in groundwater and thermal gases. The fluoride concentration of groundwater

varies greatly depending on the geological setting and type of rocks. The most common fluorine-bearing minerals are fluorite, apatite and micas. Therefore fluoride problems tend to occur in places where those minerals are abundant.

Sedimentary rocks have a fluorine concentration from 100 ppm (limestone) up to 1000 ppm (shale) (Frencken, 1992). In carbonate sedimentary rocks the fluorine is present as fluorite. Clastic sediments have higher fluorine concentration as fluorine is concentrated in mica and illites in clay. High concentrations may also be found in sedimentary phosphate beds or volcanic ash layers (Frencken, 1992).

Metamorphic rocks have a fluorine concentration from 100 ppm (regional metamorphic) up to more than 5000 ppm (contact metamorphic). In these rocks the original minerals are enriched with fluorine by metamorphic processes.

Igneous rocks have a fluorine concentration from 100 ppm (ultramafic) up to > 1000 ppm (alkaline) (Frencken, 1992). In general fluorine accumulates during magmatic crystallization and differentiation processes of magma. Consequently, the residual magma is often enriched in fluorine. Groundwater from crystalline rocks, especially (alkaline) granites (deficient in calcium) contribute to the high fluoride concentration.

5.2 Contact time

The ultimate concentration of fluoride in groundwater largely depends on reaction times with aquifer minerals. High fluoride concentrations can build up in groundwater which has long residence times in the aquifers. Such ground waters are usually associated with deep aquifers and a slow movement. Shallow aquifers that contain recently infiltrated rainwater usually have low fluoride concentration.

5.3 Climate

Arid and semi-arid region are prone to high fluoride concentration. Here, groundwater flow and the reaction times which rocks are long. The fluoride contents may increase during evaporation if solution remains in equilibrium with calcite and alkalinity is greater than hardness. Dissolution of evaporative salts deposited and arid zone may be important source of fluoride.

5.4 Chemical composition of groundwater

High fluoride groundwater is mainly associated with a sodium-bicarbonate water type and relatively low calcium and magnesium concentrations. Such water usually have high pH values (above 7).

6. Surface geology of study area

The surface geology (Figure 5) of the study area consists of the following formation:

- Recent Quaternary: Gravel, sand, clay and loess.
- Late- Recent Quaternary: Gravel, sand, clay and loess.
- Late Quaternary :Sand, clay and clay sand
- Middle Quaternary: Loam and travertine.
- Early Quaternary: Gravel, sand, siltstone, sandstone, breccia and limestone.

- Middle Miocene: Siltstone, sandstone and limestone.
- Early Miocene: Red clay siltstone and limestone.
- Eocene: Conglomerate, siltstone and sandstone.
- Paleocene: Marl, siltstone, gypsum and conglomerate.
- Late Cretaceous: Siltstone, sandstone, conglomerate and limestone.
- Early Cretaceous: Siltstone, sandstone, marl and limestone.
- Ordovician: Shale, sandstone and cherty.

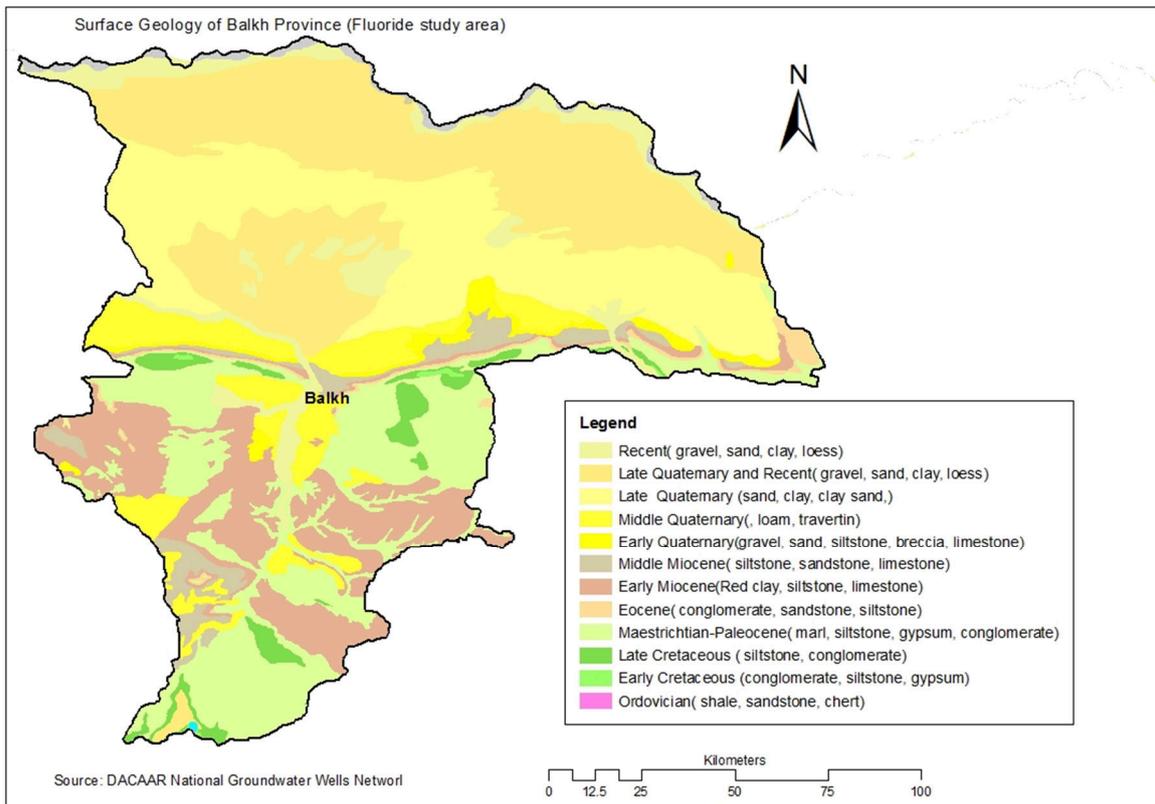

Figure 5 Surface geology of study area

6.1 Study Area

The study area is Balkh province which is located in the north part of Afghanistan. It is bordered with Tajikistan, Uzbekistan and Turkmenistan. It has semi- arid climate with major day-time and night-time fluctuations. The winter is characterized by low temperatures of less than -14 °C while the summer is dominated by high temperatures of more than 45 °C. The rainfall and snowfall are the main source of groundwater and surface water in the study area, and the area receives an average 150 mm rainfall. Agriculture and livestock are the main occupation of the people and are backbone of the rural community. The location of study is shown in the Figure 6.

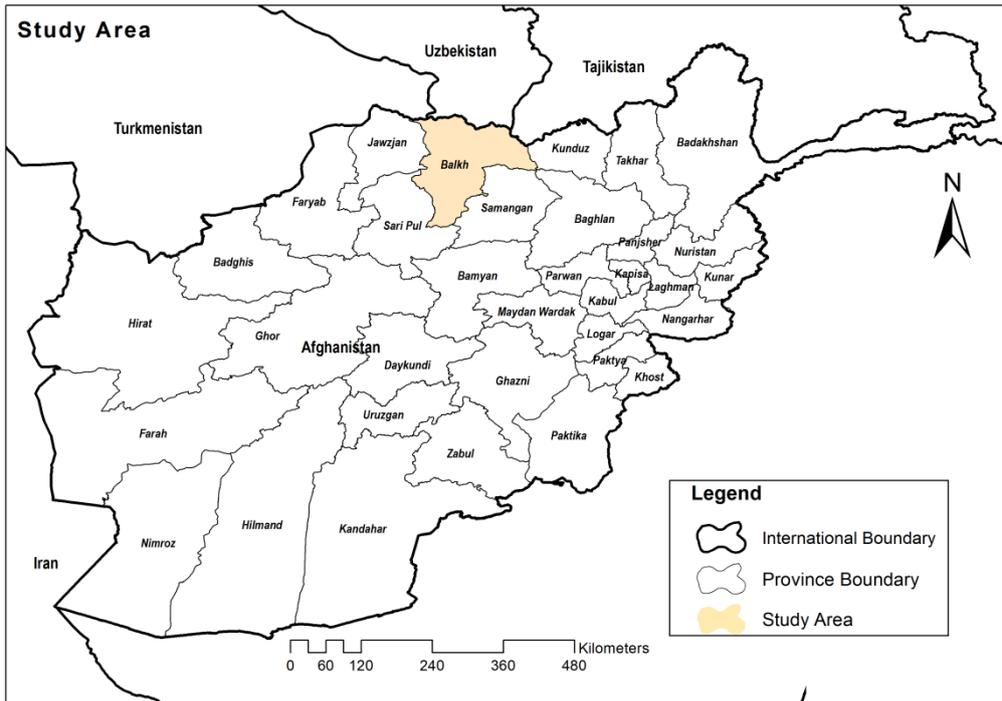

Figure 6 Location map of study area

6.2 Field investigation

The field investigation carried out in February-March, 2014 and the water samples were collected from water points such as tube well (TW) Dug well(DW), Spring, Stand Post (SP) and Balkhab and Khulm River. The water samples were transferred by plastic container for analysis of physical and chemical parameters using the standard procedure. The water sample locations were geo-referenced using geographical position system (GPS). The water points sampling location is mapped and presented in the Figure 7. An overview of the location and fluoride along with water quality analyzed parameters is presented in Annex 1.

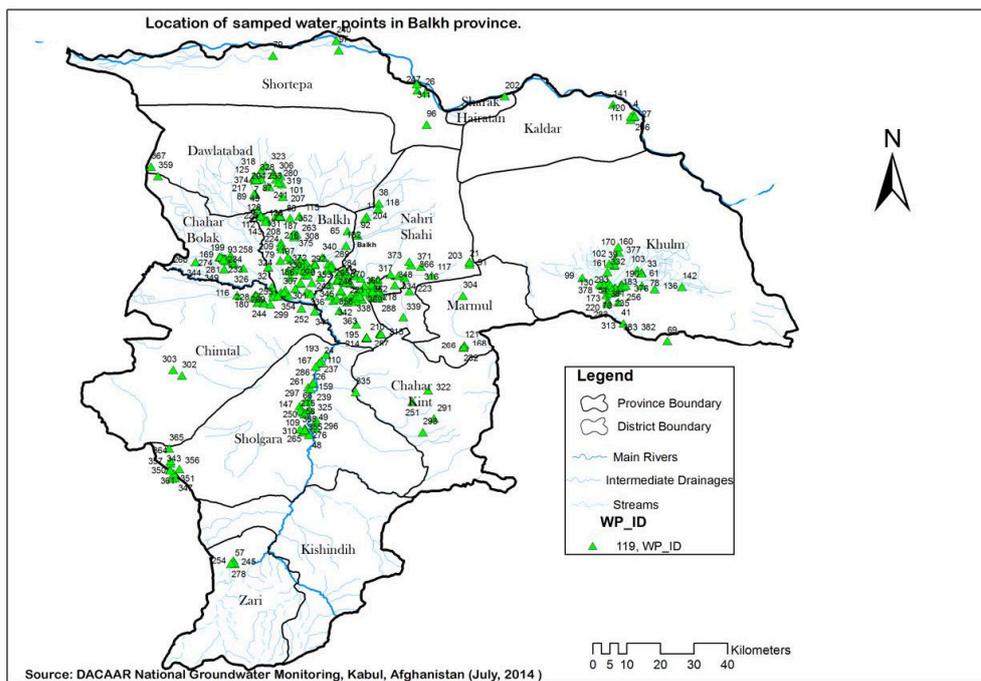

Figure 7 Location of water sample sites in Balkh Province

6.3 Field parameters

The position of each water point was obtained by using GPS. Measurements of water table, pH, electrical conductivity (EC), turbidity, temperature were made on site according to the DACAAR data collection procedure by using pH/conductivity meter and water level indicator.

6.4 Sampling of water points

The water samples were collected from TW, DW, SP, spring and Balkhab and Khulm Rivers. The collected water samples were transferred by plastic container to the DACAAR water quality analysis laboratory for analysis of chemical parameters. All the collected water samples were preserved at 4 °C prior to analyses.

7. Results and discussions

The finding of the study focus on fluoride concentrations along with other main physical and chemical parameters that they are potentially affect the health of inhabitants in the rural areas of Balkh province. Results of physical field measurement and chemical analysis of water samples from water point in Balkh province are presented in the annex 1. The discussion of the study focus on major ions chemistry, hydro-chemical process and correlations analysis.

The spatial distribution level of fluoride concentration along with other water quality parameters mapped by using arc GIS 10.2 and the inverse distance weighted method was used to interpolate the distribution of fluoride concentration along with other water quality parameters in groundwater.

7.1 Fluoride contamination

7.1.1 Fluoride contamination In Afghanistan

5,174 chemical analyzed data from UNICEF, ECHO, WASH project and National GMWs network evaluated and mapped. The results show that the fluoride concentration varied between 0.01 mg/l (Shahri Naw, Kabul city) and 15 mg/l (Wara kalli, Gurbuz district of Khost province). A fluoride spatial distribution level in the groundwater of Afghanistan is shown in annex 2.

21% of analyzed water samples from drinking water points exceeded the NDWQS of 1.5 mg/l. The percentage of fluoride distribution levels is shown in the Figure 8.

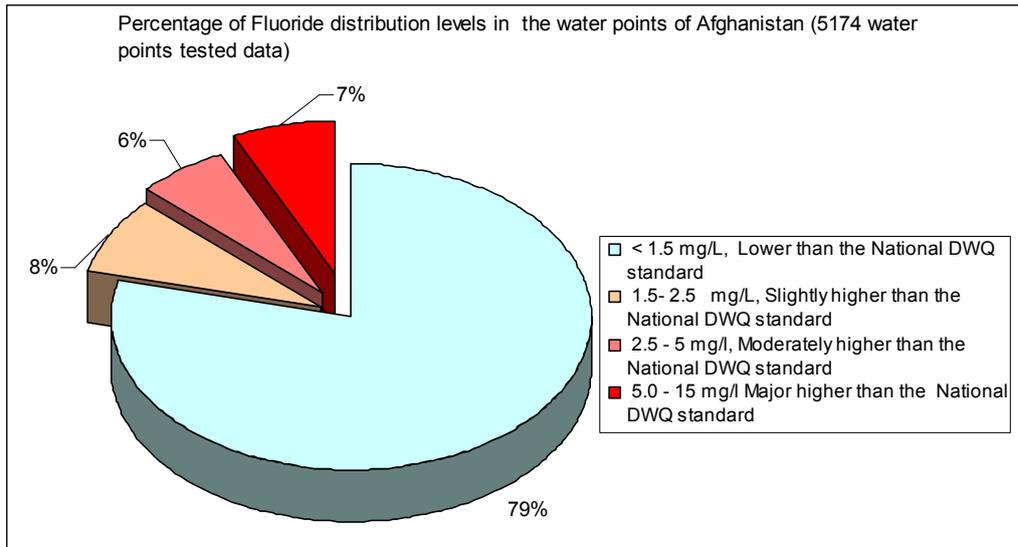

Figure 8 Percentage of fluoride distribution

7.1.2 Fluoride contamination in Balkh province

The fluoride value of water points in the study area varied from 0.020 mg/l (WP_Code 337) to 12.900 mg/l (WP_Code 235). The fluoride concentration in groundwater also varied according to the depth. In plain areas (Nahri Shahi, Dawlatabad, Chahar Bolak, Chimtal, Dehdadi, Khulm, Mazari Sharif, Kaldar, Marmul districts), the upper part of aquifer sediment (approximately to the depth of 85 m) consist of silt clay, sand clay and clay has saline and brackish water with high fluoride concentration, the lower part of aquifer sediments consist of sand and gravel has fresh water with low fluoride concentration. The fluoride concentration also varied over time (Fig 9).

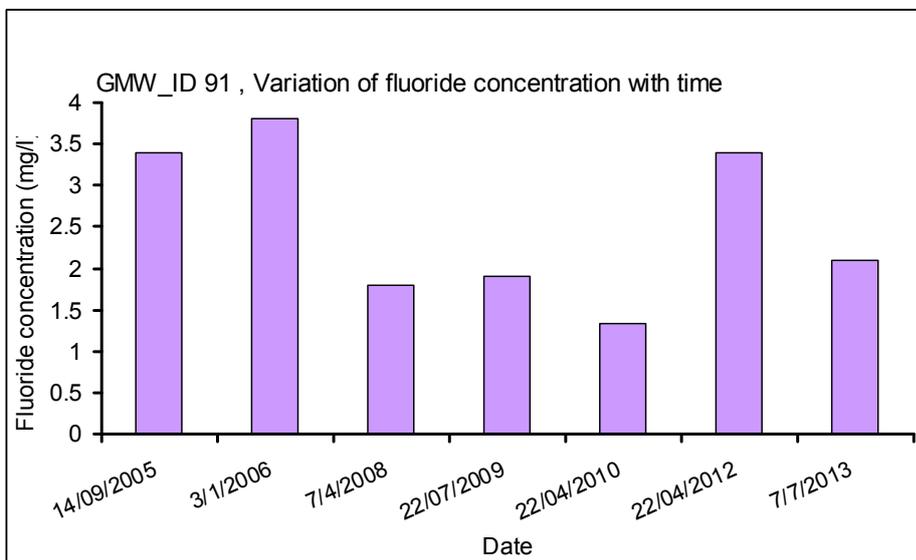

Figure 9 Variation of fluoride concentration over time

The spatial distribution level of fluoride concentration mapped and it's shown in annex 3 and the fluoride concentration interpolated contour lines mapped using arc GIS 10.2 (spatial analyst) and presented in annex 4.

38% of analyzed water samples from drinking water points exceeded the NDWQS of 1.5 mg/l. The percentage of EC distribution levels is shown in the Fig.10.

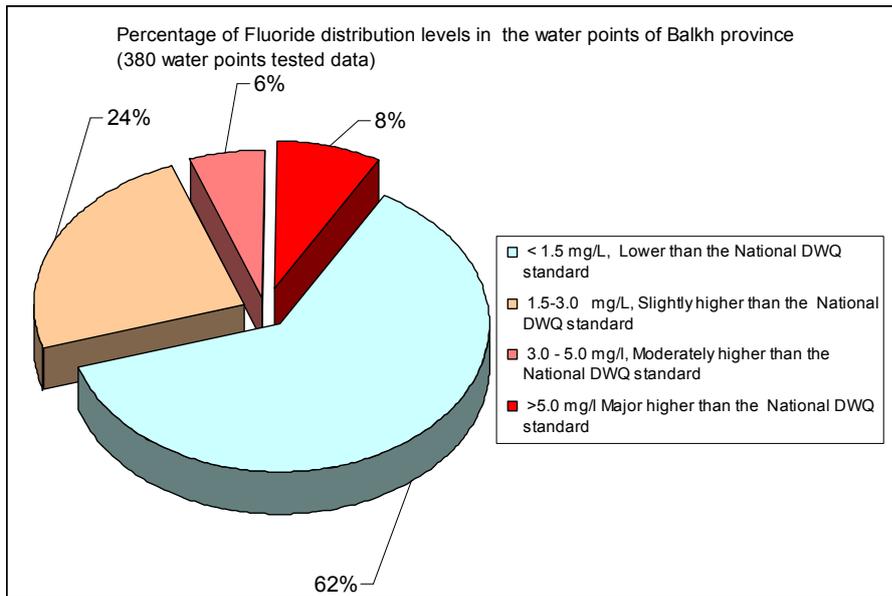

Figure 10 Percentage of fluoride levels

7.1.3 Health impact of high fluoride content drinking water in Balkh province

38% of analyzed water samples from drinking water points exceeded the NDWQS of 1.5 mg/l. Use of high Fluoride content drinking water (more than 1.5 mg/L) causes skeletal fluorosis and dental fluorosis.

DACAAR water expertise and training center carried out a health impact primary survey where drinking water points had high fluoride concentration. The people used high fluoride content drinking water, there were considered the dental fluorosis (Fig 11). During of consultant of the person in high level fluoride content areas there are no information about skeletal and crippling fluorosis.

Figure 11 Dental fluorosis in Balkh Province

7.2 Other water quality parameters of concern

7.2.1 Power of hydrogen (pH)

pH is a term used to express the intensity of the acid and alkaline condition of a solution or water. The pH value of water points in the study area found values between 6.19 (WP_Code 260) to 8.6 (WP_Code_ 366) and most of water samples indicated an alkaline characteristic. The pH of River water varied from 7.56 to 8.16 (Annex 1).

7.2.2. Electrical conductivity (EC)

EC is a measure of water capacity to convey electric current. It signified the amount of total dissolved solids. The presence of high EC values in water indicates the presence of high amount of dissolved organic constituents in ionized form .EC is an indicator of degree of mineralization of water.

The concentration of EC in water samples collected in the study area range from 320 $\mu\text{S}/\text{cm}$ (WP_Code 320) to 25,600 $\mu\text{S}/\text{cm}$ ((WP_Code 126) and the median value is 1,391 $\mu\text{S}/\text{cm}$. Values are generally less than 1,000 $\mu\text{S}/\text{cm}$ along up gradient hydro geologic boundaries. Suggesting the natural processes of chemical weathering (water rock interaction) is dominant and impacts the major ion chemistry. The highest values concentrations of EC are occurred in the down gradient (lowland) and the natural chemical process such as evaporation and ions and cat ion exchange would be influential .The EC of surface water (River) varied from 479 $\mu\text{S}/\text{cm}$ (Balkhab River) to 1,887 $\mu\text{S}/\text{cm}$ (Khulm River).

In general the areas with high EC or TDS in groundwater overlap the areas with high fluoride concentration.

The spatial distribution level of EC concentration mapped is shown in annex5 and the EC values interpolated contour lines are presented in annex 6.

Our analysis result revealed that 21% of tested water samples from drinking water points exceeded the limit of 3,000 $\mu\text{S}/\text{cm}$ recommended by NDWQS, however, 44% of analyzed water samples exceeded the limit 1,500 $\mu\text{S}/\text{cm}$ recommended by WHO. Because of the acute shortage of safe drinking water in Afghanistan, the EC of drinking water up to 3,000 $\mu\text{S}/\text{cm}$ is tolerance for human consumption. The percentage of EC distribution levels is shown in the Figure 12.

Percentage of EC distribution levels in the water points of Balkh province (380 water points tested data)

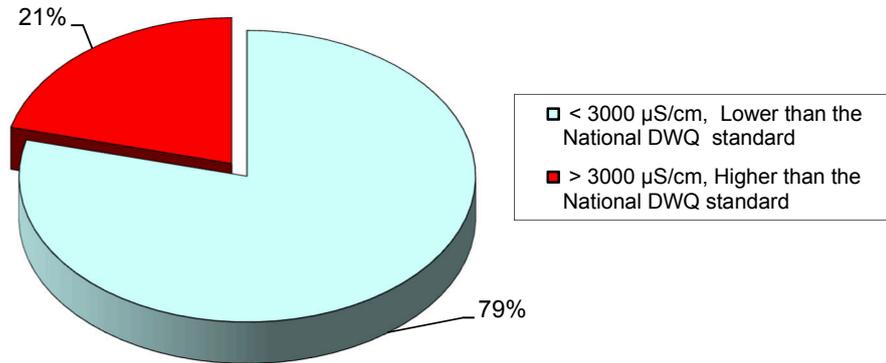

Figure 12 Percentage of EC levels

7.2.3 Arsenic

The WP_Code 122 (0.001mg/l), WP_Code 313(0.001), WP_Code 373(0.001 mg/l), and WP_Code 313(0.001 mg/l) (Annex 1) were observed to have an arsenic concentration but the concentration values are lower than national DWQ standard of 0.04 mg/l of As.

7.2.4 Sulphate

The sulphate concentration value of water points in the study area varied from 11 mg/l (WP_Code 322) to 5200 mg/l (WP_Code 349)(Annex 1).The sulphate spatial distribution level and its concentration interpolated contour lines are presented in annexes7 and 8.

35% of analyzed water samples from drinking water points are exceeding the NDWQS of 250 mg/l. The percentage of sulphate distribution levels is shown in Figure 13.

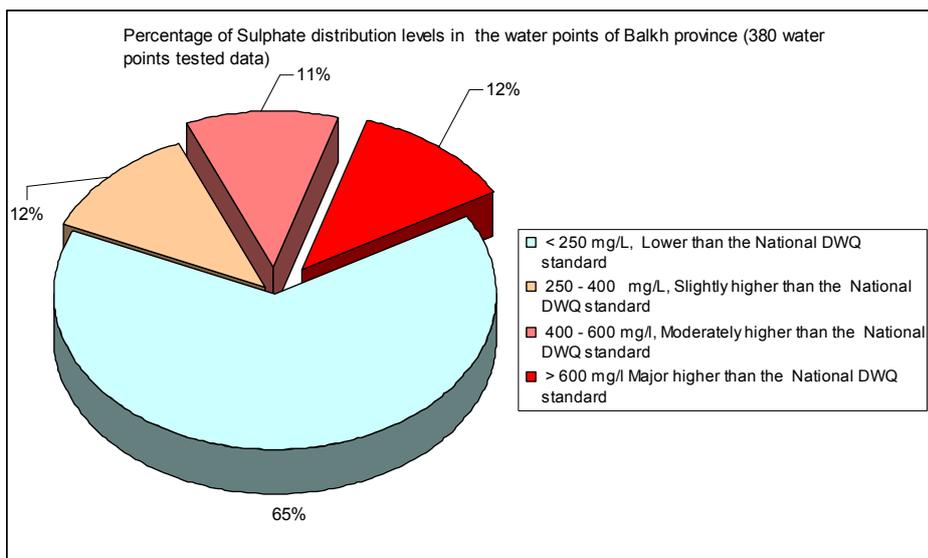

Figure 13 Percentage of sulphate levels

Using of high sulphate content drinking water (more than 400 mg/L) causes severe diarrhea and loss of body fluid of users and can be dangerous for children, however given bitter taste

to the water [6]. High concentration of sulphate in the water we drink can have a laxative effect when combined with calcium and magnesium, the two most common constituent of hardness. Bacteria, which attack and reduce sulphates, form hydrogen sulfide gas.

7.2.5 Nitrate

The Nitrate concentration of analyzed water samples ranged from 0.01 mg/l (WP_Code 325) to 264 mg/l (WP_Code 233) (Annex 1). The nitrate spatial distribution levels is presented in annex 9.

9% of analyzed water samples exceeded the NDWQS of 250 mg/l. The percentage of nitrate distribution levels is shown in the Figure 14.

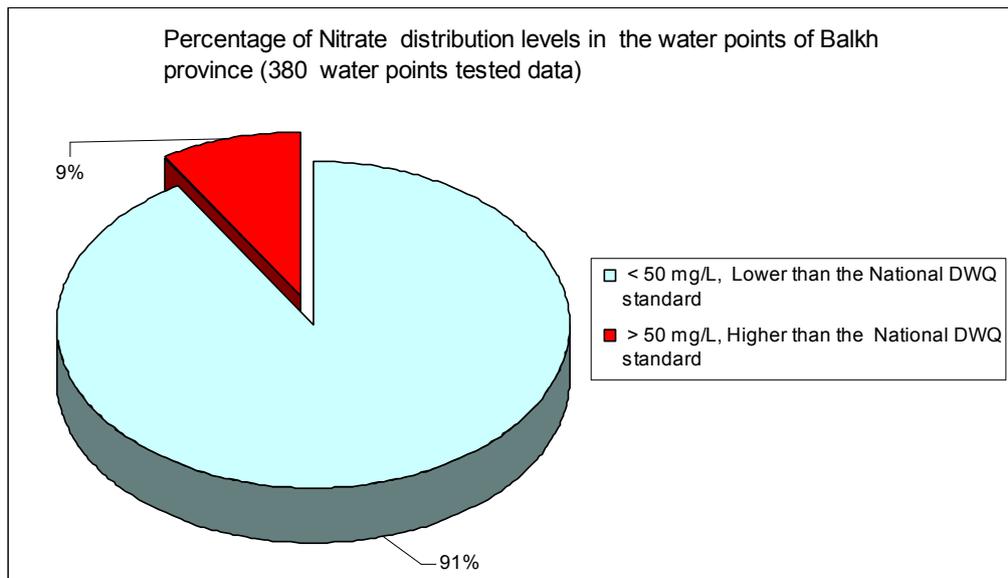

Figure 14 Percentage of Nitrate level

Nitrate can cause health problems for infants, especially those six months of age and younger. Nitrate interferes with their blood's ability to transport oxygen. This causes an oxygen deficiency, which results in a dangerous condition called *methemoglobinemia*, or "blue baby syndrome". The most common indication of nitrate toxin is bluish skin coloring, especially around the eyes and mouth. Infants six months of age and younger and pregnant and nursing women should avoid consumption of water high in nitrate. Toxic effects occur when bacteria in the infant's stomach convert nitrate to more toxic nitrate. Some scientific studies suggest a linkage between high nitrate level in drinking water with birth defects and certain types of cancer.

According to the US Environmental Protection Agency (EPA) long-term exposure to water with high nitrate levels can cause diuresis (excessive discharge of urine), increased starchy deposits, and hemorrhaging (flow of blood) of the spleen. People with heart or lung disease reduced acidity maybe more vulnerable to the toxic effects of nitrate than others.

7.2.6 Sodium

The Sodium concentration value of analyzed water samples ranged from 22mg/l (WP_Code 154) to 980 mg/l (WP_Code 349) (Annex 1). The Sodium spatial distribution levels and its concentration interpolated contour lines are shown in annex 11 and 12.

43% of analyzed water samples exceeded the National Drinking Water Quality Standard (DWQS) standard of 200 mg/l. The percentage of nitrate distribution levels is shown in Figure 16.

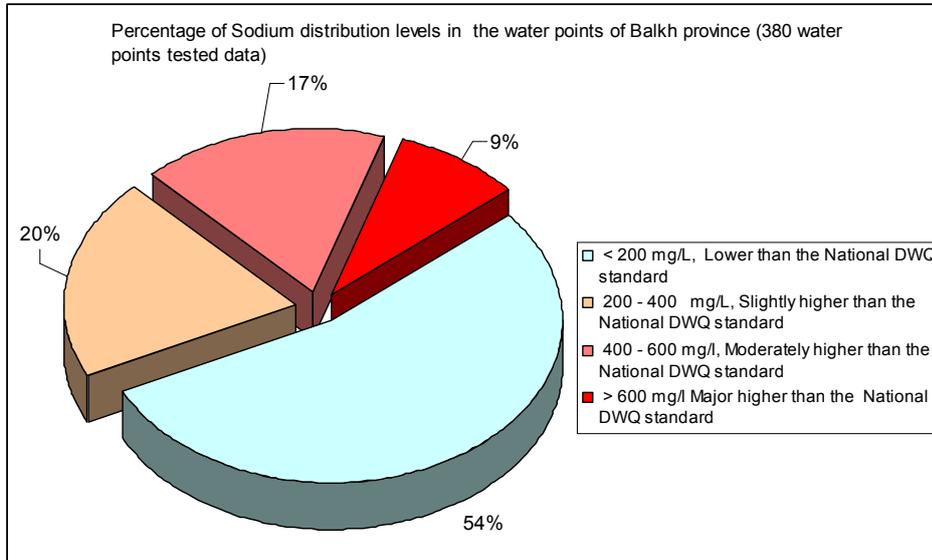

Figure 15 Percentage of Sodium levels

A high content of sodium in drinking water is injurious to health (increases blood pressure).

7.2.7 Chloride

The Chloride concentration value of analyzed water samples ranged from 2.1 mg/l (WP_Code 378) to 546 mg/l (WP_Code 235) (Annex 1). The chloride spatial distribution levels and its concentration interpolated contour lines are presented in annex 13 and 14.

31% of analyzed water samples exceeded the NDWQS of 250 mg/l. The percentage of Chloride distribution levels is shown in Figure 17.

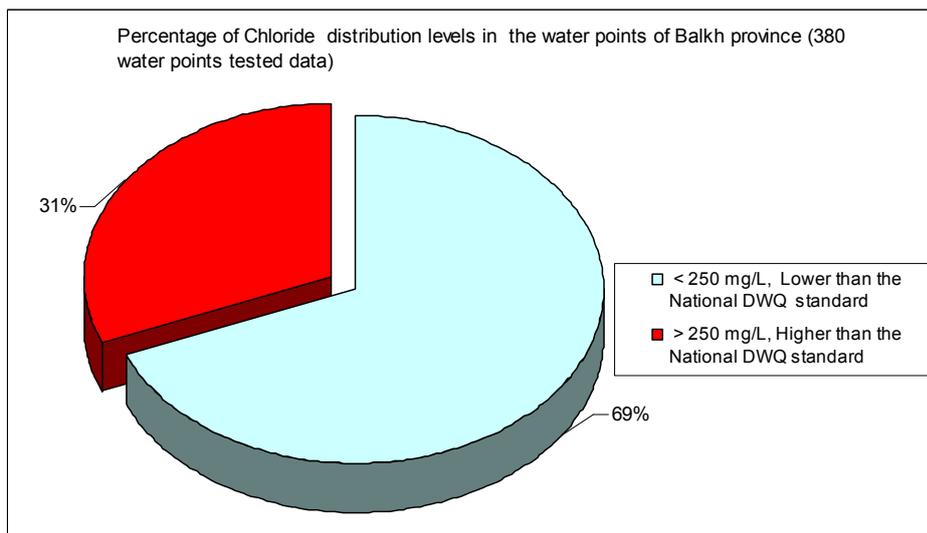

Figure 16 Percentage of Chloride level

Water with high chloride concentration gives saline taste and it can cause considerable damage to the body's fluid balance. One of the negative effects of highly saline water is also the corrosion of metal and destroys concrete elements.

7.2.8 Calcium

The Calcium concentration value of analyzed water samples ranged from 7.3 mg/l (WP_Code 246) to 786 mg/l (WP_Code 366) (Annex 1). The Calcium spatial distribution levels and its concentration interpolated contour lines are presented in annex 15 and 16.

43 of analyzed water samples exceeded the National Drinking Water Quality (DWQ) standard of 70 mg/l. The percentage of Calcium distribution levels is shown in Figure 18.

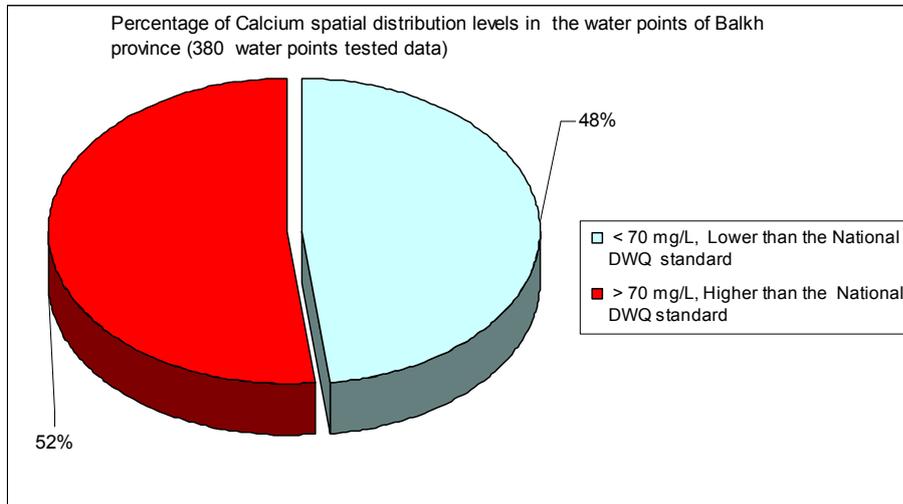

Figure 17 Percentage of Calcium level

7.2.9 Magnesium

The Magnesium concentration value of analyzed water samples ranged from 1.00 mg/l (WP_Code 373) to 920 mg/l (WP_Code 342) (Annex 1). The Magnesium spatial distribution levels and its concentration interpolated contour lines are presented in annex 17 and 18.

88% of analyzed water samples exceeded the NDWQS of 30 mg/l. The percentage of Magnesium distribution levels is shown in Fig.19.

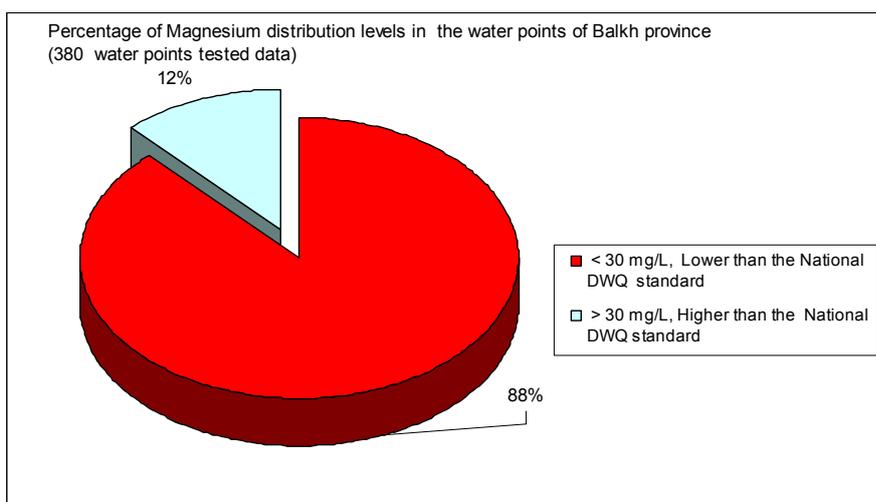

Figure 18 Percentage of Calcium level

Using of high Magnesium content drinking water (more than 150 mg/L) causes severe diarrhea among the users and gives a bitter taste to the water.

7.3 Major ions chemistry

Piper diagram is particularly useful comparing (chemical relationship) large number of water samples because; it enables several chemical parameters to be shown at the same time.

The Fig. 20 basically shows that the chemical composition of groundwater evolves from a slightly mineralized (natural) Ca-HCO₃ water type (up gradient/ up land) to a high mineralized (polluted) Mg- Na -SO₄- Cl and Na - SO₄- Cl water types (down gradient/plain areas). Between them (natural and polluted water types) densely clustered mixed Mg-Na-HCO₃- SO₄, Mg-Na-HCO₃-SO₄, Mg-Na-HCO₃-SO₄-Cl, and Mg-Ca-HCO₃-SO₄-Cl water types. These different chemical compositions are consistent with weathering of calcite, dolomite, silicate and other minerals.

The dominant cat-ions in the water samples is Na⁺ > Mg⁺² > Ca⁺². The dominant anions in the water samples is HCO₃⁻² > SO₄⁻² > Cl⁻. In general the Na⁺ > Mg⁺² > Ca⁺² indicates cat-ion exchange trend. The dominance of in sodium could be due to dissolution of some miner cat-ion exchange. The high sodium concentration and alkaline environment are the factors for high fluoride concentration in the groundwater of the study area.

The dominance anion in the majority of the samples of the study area is bicarbonate (HCO₃⁻) ion with a considerably increasing of sulphate (SO₄⁻²) and chloride (Cl⁻) ions. The dominant source of bicarbonate ion is mainly due to the strong influence of the carbonate rocks (calcite and dolomite) aquifer that occurs in the south and south-east part of the study area.

The source of high sulphate ion most probably results from dissolution of evaporative gypsum and anhydride mineral within the carbonate rock that is considered in the Paleocene formation in the south and east parts of Balkh province.

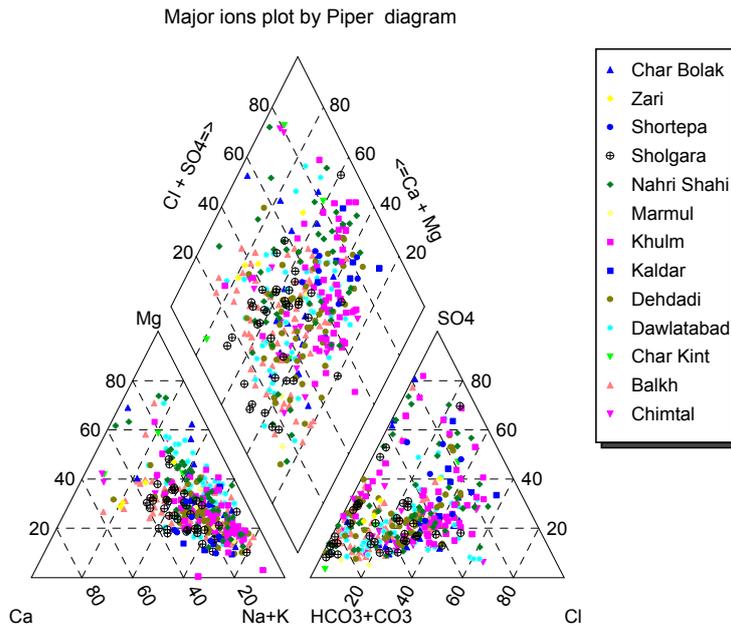

Figure 19 Piper Diagram of Groundwater

7.4 Hydro-geochemical process

The physical and chemical analyzed parameters were graphically interpreted and evaluated by AquaChem (2012.1) to identify the hydro-geochemical process and mechanism in the aquifer system.

In general, it is expected that the evaporation process would cause an increase in the concentration of sodium in groundwater, however the graphic interpretation result indicates that originally the weathering of silicate and carbonate rock is one of the important processes for the concentration of fluoride and sodium ions in the groundwater of the study area which are responsible for high fluoride and sodium concentration.

If the evaporation process is dominant, assuming that no minerals precipitated, the Na/Cl ratio versus EC value would be unchanged [7]

The plot of Na/Cl versus EC (Fig. 21) gives a horizontal line, which would then be an effective indicator of concentration by evaporation, however the Na/Cl versus EC plot is not a horizontal line and the result shows that the evaporation process is not dominant.

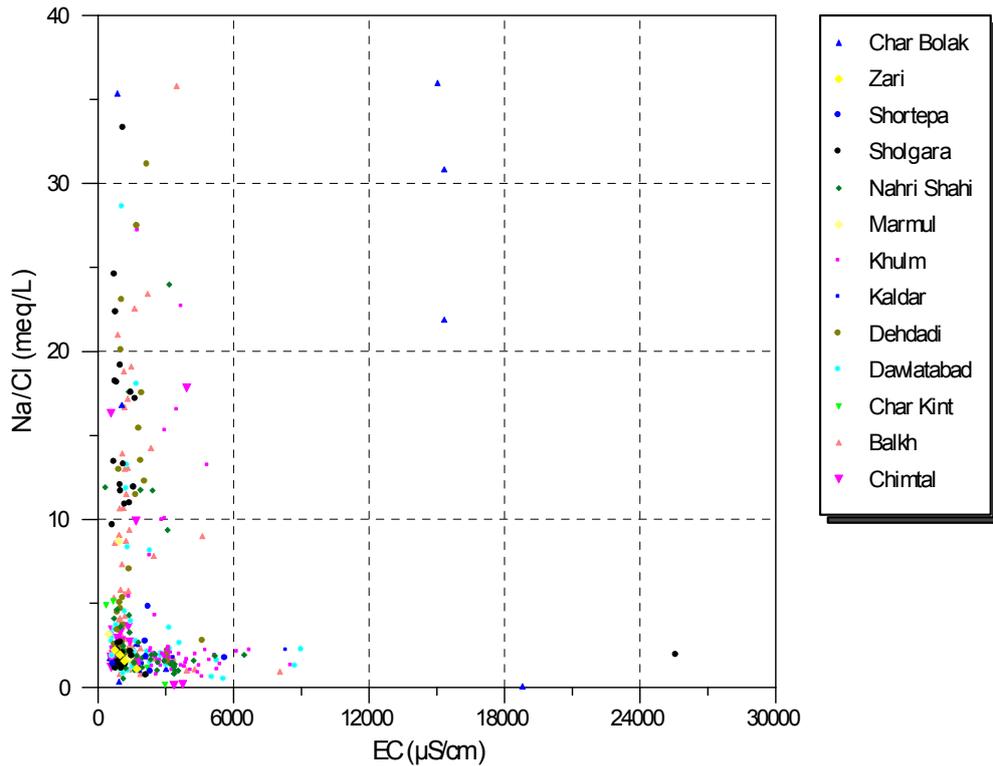

Figure 20 Plot of Na/Cl versus EC

If halite (salt) dissolution is responsible for Na ions, the Na/Cl molar ratio should be approximately equal to 1, whereas ratio greater than 1, therefore, it is interpreted that the high sodium concentration in the groundwater originally released from silicate weathering reaction [8]. The molar ratio of Na/Cl versus Cl can be used to reflect ion exchanges degree [9].

As most of water samples have the molar ratio of Na/Cl versus Cl greater than 1 (Fig.22) and Na/Cl ratio showed a decreasing trend in chloride concentration. The reason for ion exchange in high chloride groundwater was that sodium concentration increase due to evaporation and become high enough to balance the adsorbed sodium ion for ion exchanged cat-ions, also the increase in EC would be driving force for cat-ion exchange between calcium and adsorbed sodium ions. In plain areas (Nahri Shahi, Dawlatabad, Char Bolak, Chintal, Dehdadi, Khulm, Kaldar and Marmul districts), the aquifer sediment consist of medium sand and fine-mid sand, gradually finer with increase in clay mineral content and could adsorb sodium ions. Therefore, calcium and magnesium ions in the water would have exchanged with sodium ions previously absorbed in the surface of clay minerals matrix due to increase in groundwater EC. This reaction decreases of calcium and magnesium ions and increase sodium concentration in groundwater.

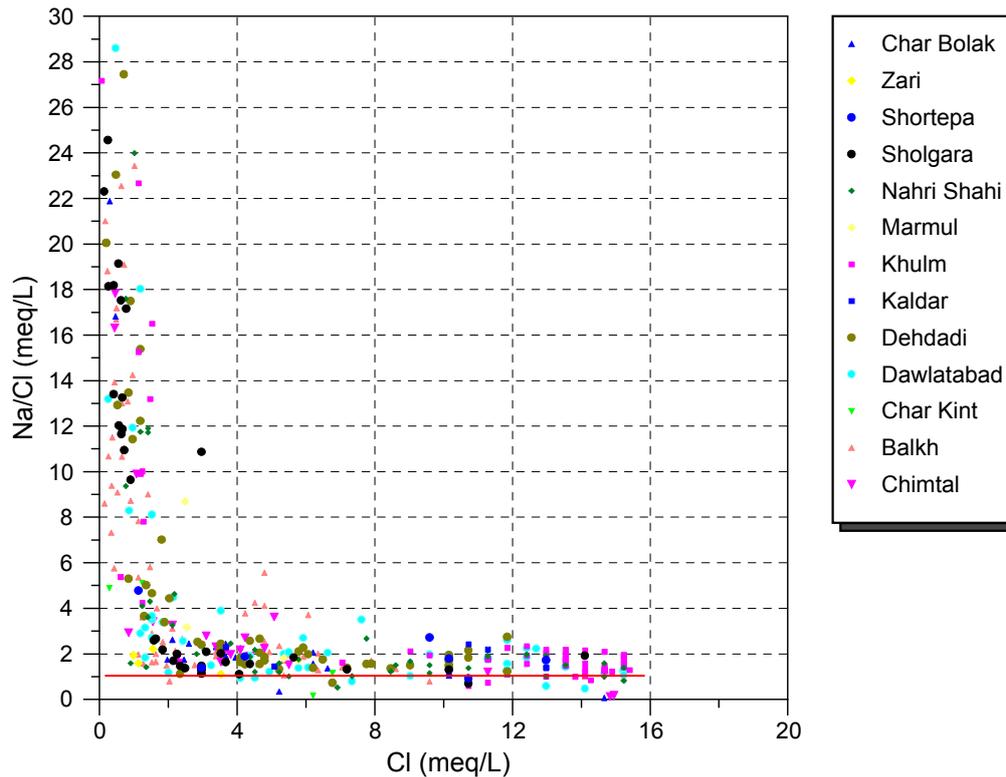

Figure 21 Plot of Na/Cl versus Cl

The sodium versus chloride (Na vs. Cl) plot (fig. 23) indicates that most of the water samples lie above the equilibrium line (1:1). The origin of excess sodium ions (Na^+) is attributed to come from weathering of silicate rocks [10, 11].

The water samples lie below the equilibrium line, indicating that evaporation process may be cause of addition of chloride due to groundwater level rises which cause more salt dissolution from soil. Sodium concentration is also being increased by ion exchange.

The cluster of raised Na/Cl concentration related to the low land (plain area). This area has saline aquifers. The long resident time of evaporation process, clay layer and capillary rise of shallow groundwater table has caused the increase of the chloride and sodium concentration.

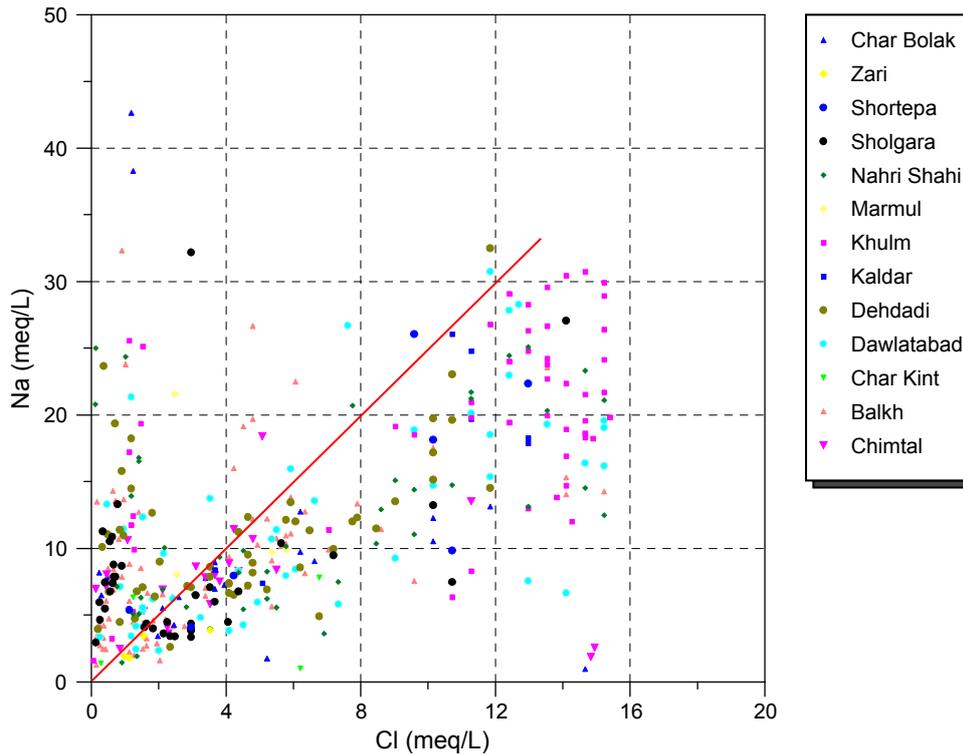

Figure 22 Plot of Na versus Cl

The study of the Ca/Mg ratio of the analyzed water samples from the study area suggest the dissolution of calcite and dolomite present (fig 24).

That is, if the ratio Ca/Mg equal 1(Ca/Mg=1), dissolution of dolomite should occur, whereas, if the Ca/Mg greater than 1(Ca/Mg>1), dissolution of calcite should occur [12].

The points clustered close or less to the line of Ca/Mg =1 indicate the dissolution of dolomite. The points clustered above to the line Ca/Mg =1 indicate the dissolution of calcite. The figure 24 shows that the dissolution of dolomite is more dominant than calcite.

Higher molar ratio of Ca/Mg>2 indicates the dissolution of silicate minerals which contribute calcium and magnesium to groundwater.

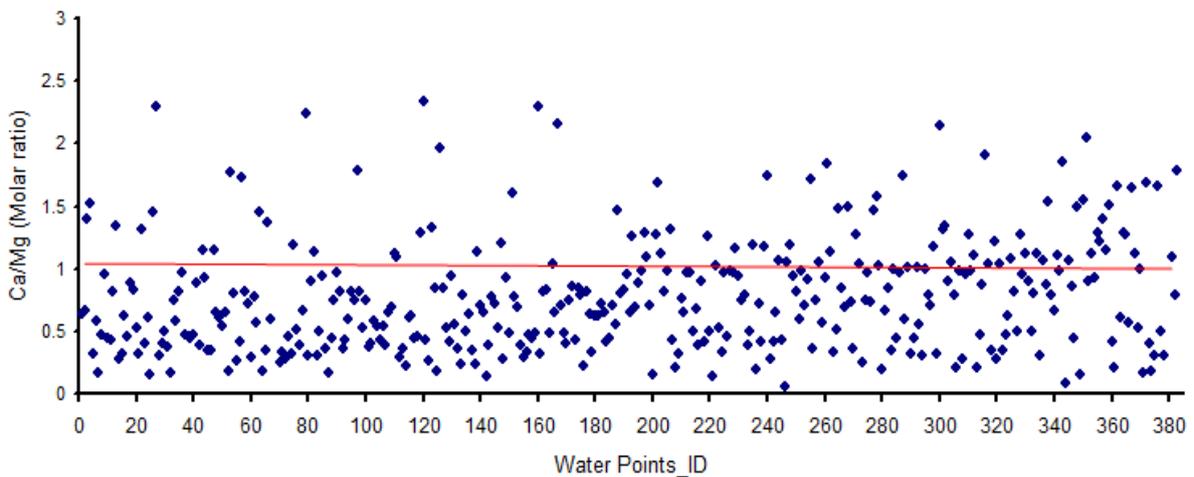

Figure 23 Ca/Mg versus water point codes

The Ca+Mg versus HCO₃+SO₄ scatter diagram [13] shows that most of water samples are falling above the equilibrium line (1:1) indicating that the carbonate weathering is the dominant process for the supply of calcium and magnesium ions to the groundwater (fig. 25). In addition to carbonate weathering, silicate weathering process is also a contributor for calcium (Ca²⁺) and sodium (Na⁺) ions in groundwater.

Possible source of sulphate could be originated due to dissolution of gypsum (Mg SO₄. 2H₂ O) and anhydrite(Mg SO₄) minerals during their long residence time.

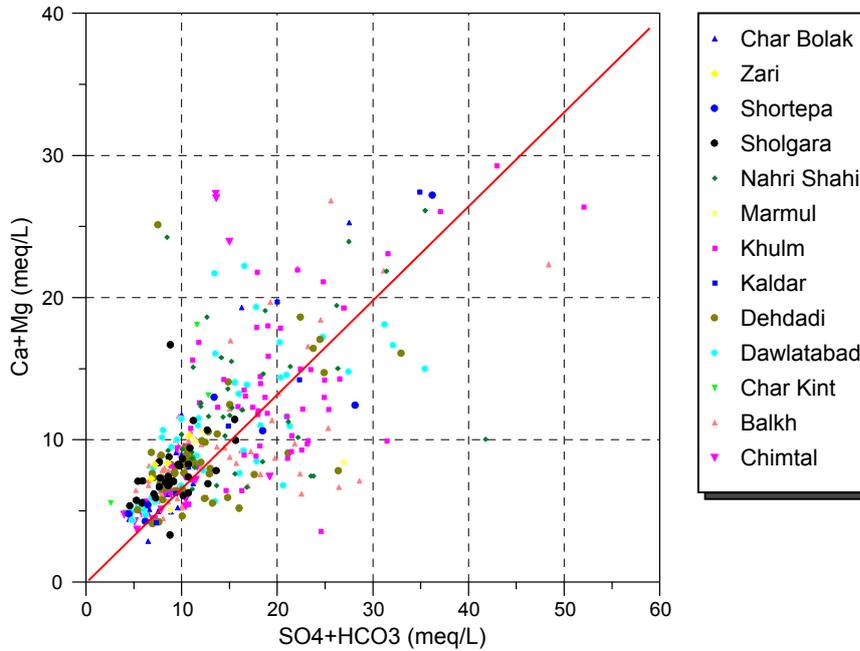

Figure 24 Ca + Mg versus HCO₃ + SO₄

7.5 Correlation analysis

For understanding the correlation mechanism of fluoride concentration in the groundwater, the correlation coefficient (r) of fluoride with pH (r= 0.02), Ca(r=0.480), Mg(r=0.560), Na(r=0.510), EC(r=0.546), SO₄(r=0.628), K(r=0.154), Cl (r=0.0457),HCO₃ (r=0.0.215),were plotted by scatter plots using Acua-Chem software.

The alkaline earth metal (Ca and Mg) show positive correlation with Fluoride (Fig.26 + 27). The positive correlation of fluoride with calcium and magnesium is expected due to high solubility of fluoride with the other ions.

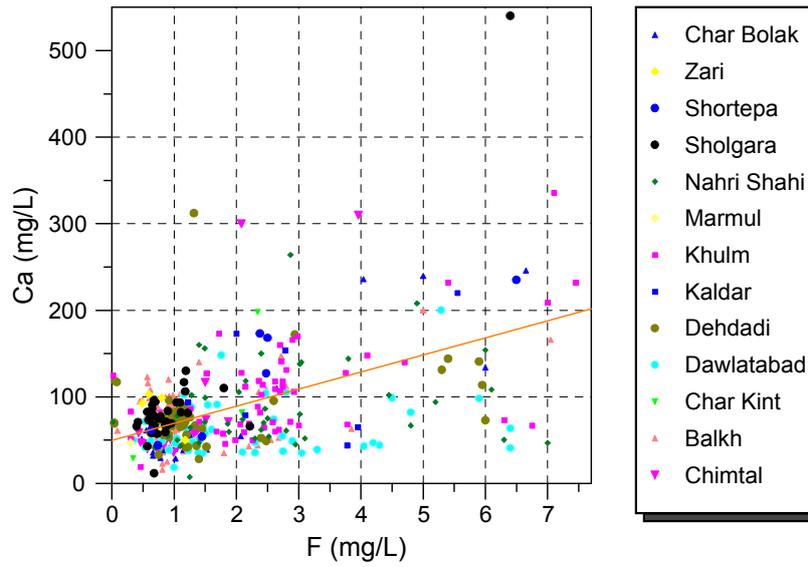

Figure 25 Correlation between calcium and fluoride

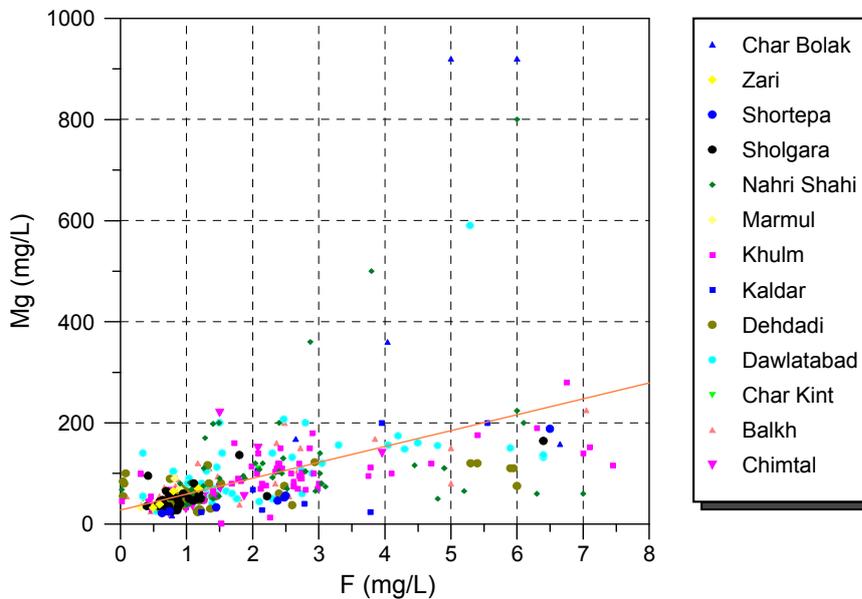

Figure 26 Correlation between magnesium and fluoride

The alkali metal Na^+ show positive correlation with Fluoride (Fig.28) in groundwater, however the K^+ shows very poor positive correlation with Fluoride in groundwater, The significant positive correlation between sodium and fluoride suggests that the sodium is mostly driven from rock weathering.

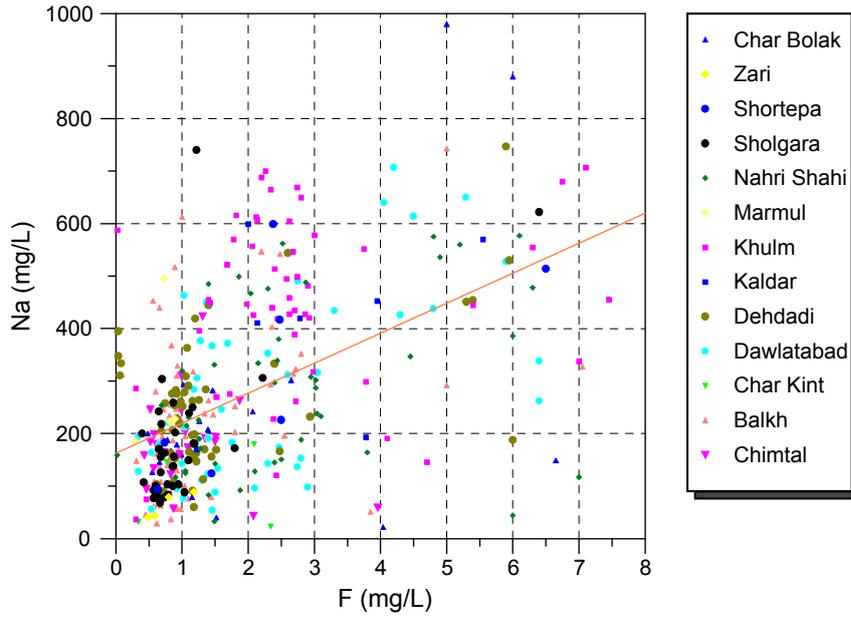

Figure 27 Correlation between sodium and fluoride

Figure 29 shows a good positive relationship between fluoride and chloride ions. This trend indicated that the evaporation process influences to the elevated fluoride concentration. Figure 30 also shows, the concentrations of chloride concentration in the most of samples are higher than 250 mg/l which suggest evaporative influence.

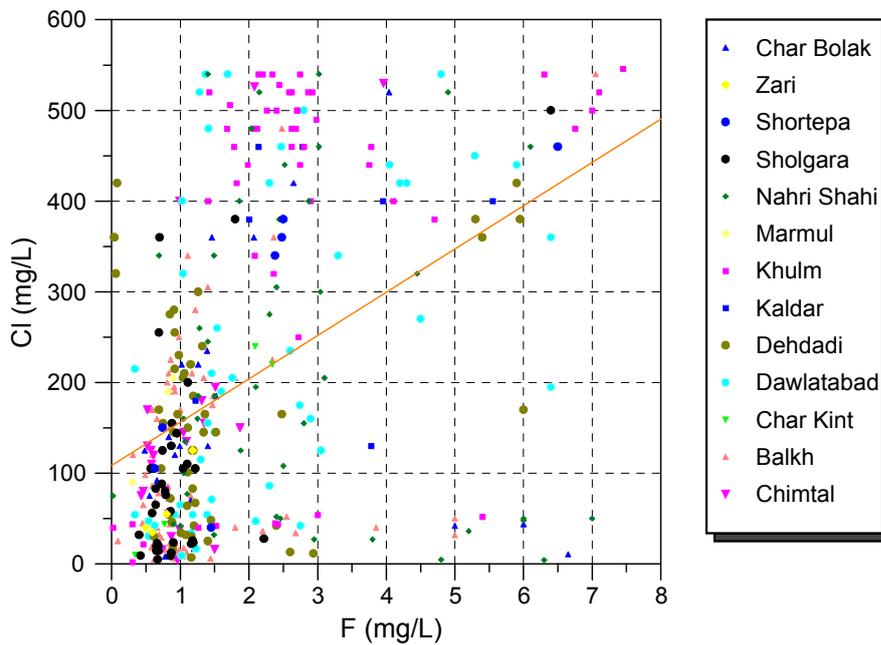

Figure 28 Correlation between chloride and fluoride

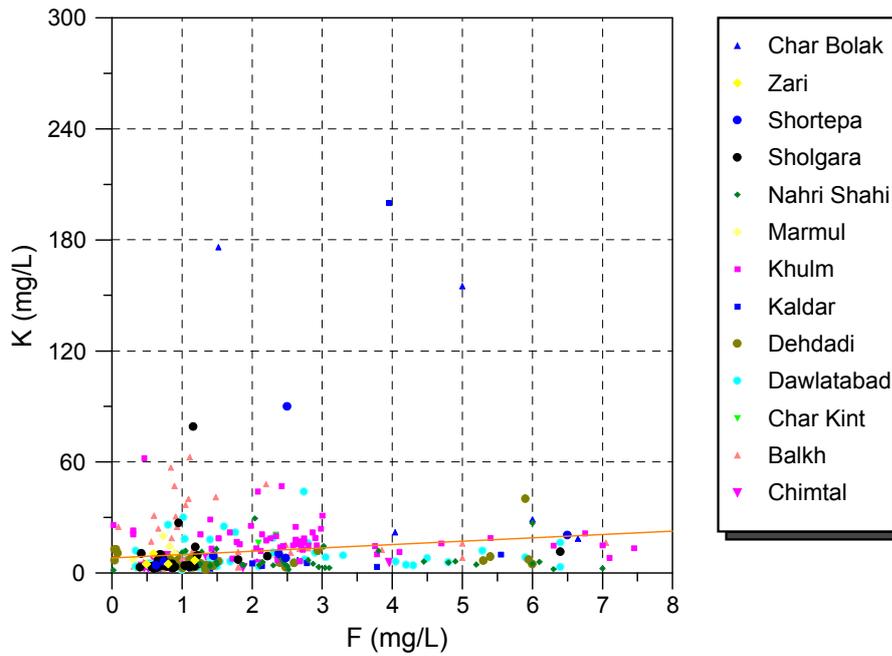

Figure 29 Correlation between potassium and fluoride

Figure 31 shows a significant positive relationship between fluoride and EC. This trend indicated where the EC value is higher, therefore observed high fluoride concentration in the groundwater.

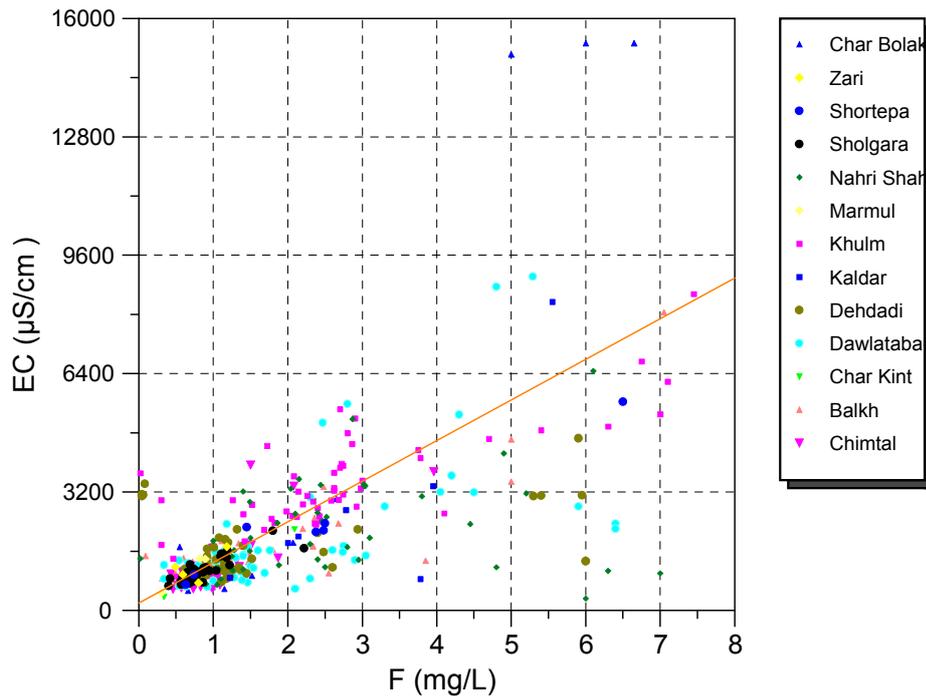

Figure 30 Correlation between potassium and EC

8. Conclusion

- Fluoride concentration in groundwater is mainly a natural occurrence influenced basically by the geologic setting and hydro geological conditions.

- Result from the groundwater of study area shows that the fluoride content of 38% analyzed water samples from drinking water points exceeded the National DWQS of 1.5 mg/l.
- In general the areas with high fluoride concentration in groundwater overlap the areas with high Electrical Conductivity (EC).
- Semi- arid characteristic climate with high temperature, low rainfall and alkaline nature of soil are the contributing factors to enhance the fluoride concentration in groundwater.
- The dominant hydro chemical processes are weathering and dissolution of fluoride-bearing minerals, evaporation, ion exchange and capillary rise and lowering water level.

9. Suggestion

- The people using drinking water with high fluoride concentration, there observed dental fluorosis, it is recommended that alternative arrangement for supply of drinking water from other safe sources to the affected villages by WASH sector may be taken as top priority.
- Encourage education and awareness' where there are the fluoride concentration is higher and potentially affects the health of people.
- Encourage research on cheap ways of fluoride removal technologies that are applicable. This could include precipitation, adsorption, ion exchange, membrane filtration processes and distillation methods.
- Encourage research for finding alternative water sources for provision of safe drinking water.
- Fluoride concentration can be diluted by induce groundwater recharge techniques construction.

Annex 2 Fluoride Spatial Distribution Level in Groundwater Afghanistan

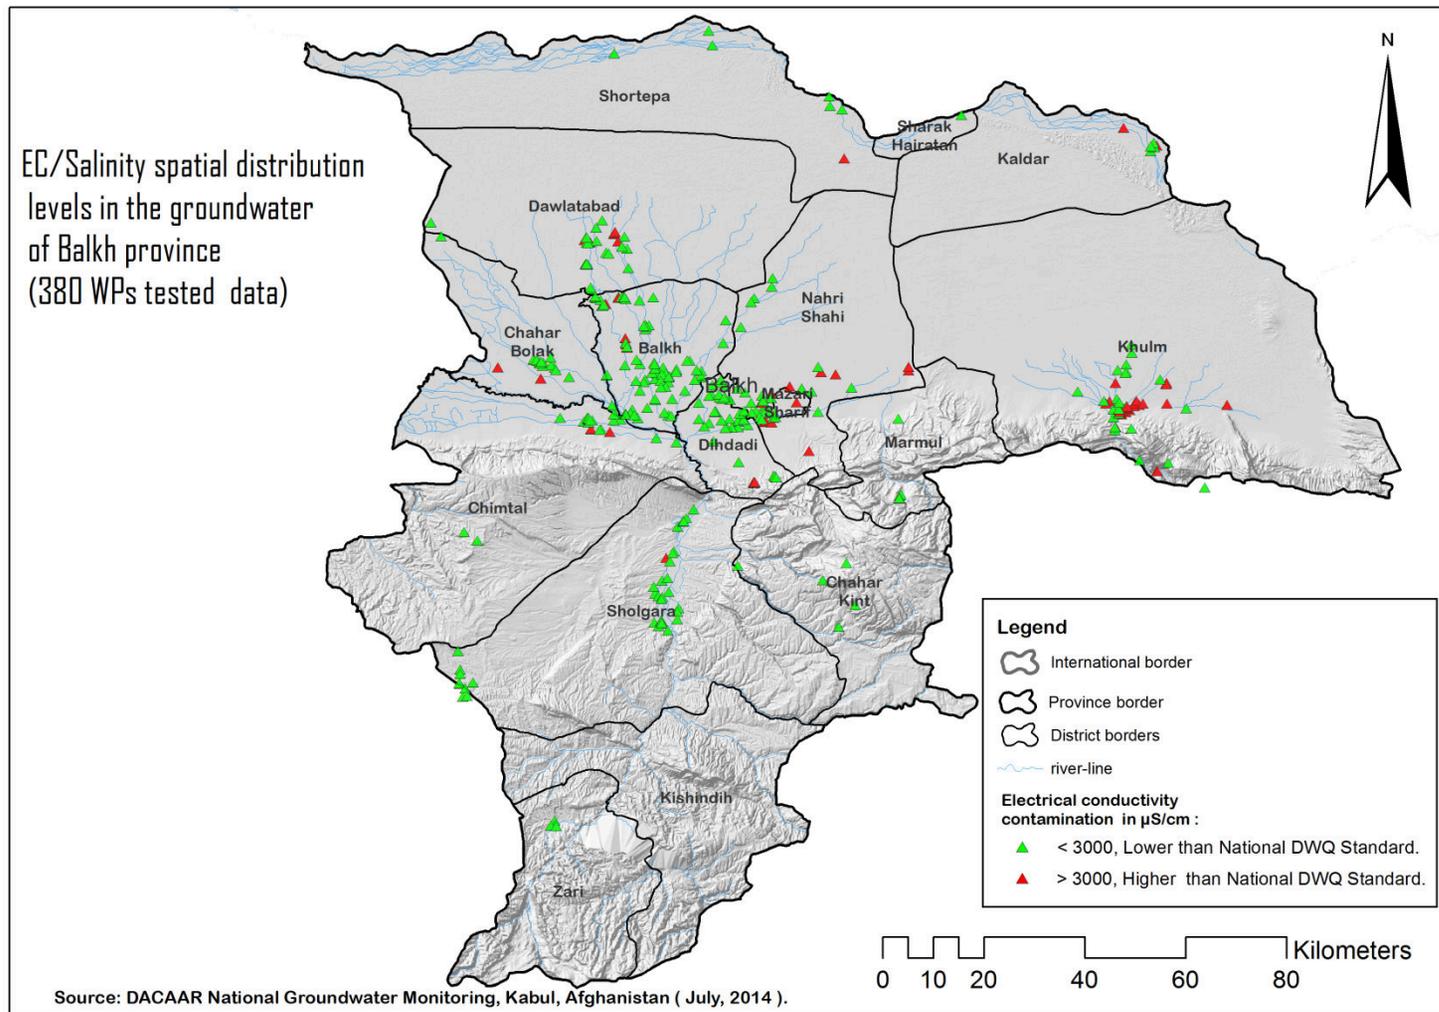

Annex 3 Fluoride Spatial Distribution Level in Groundwater in Balkh

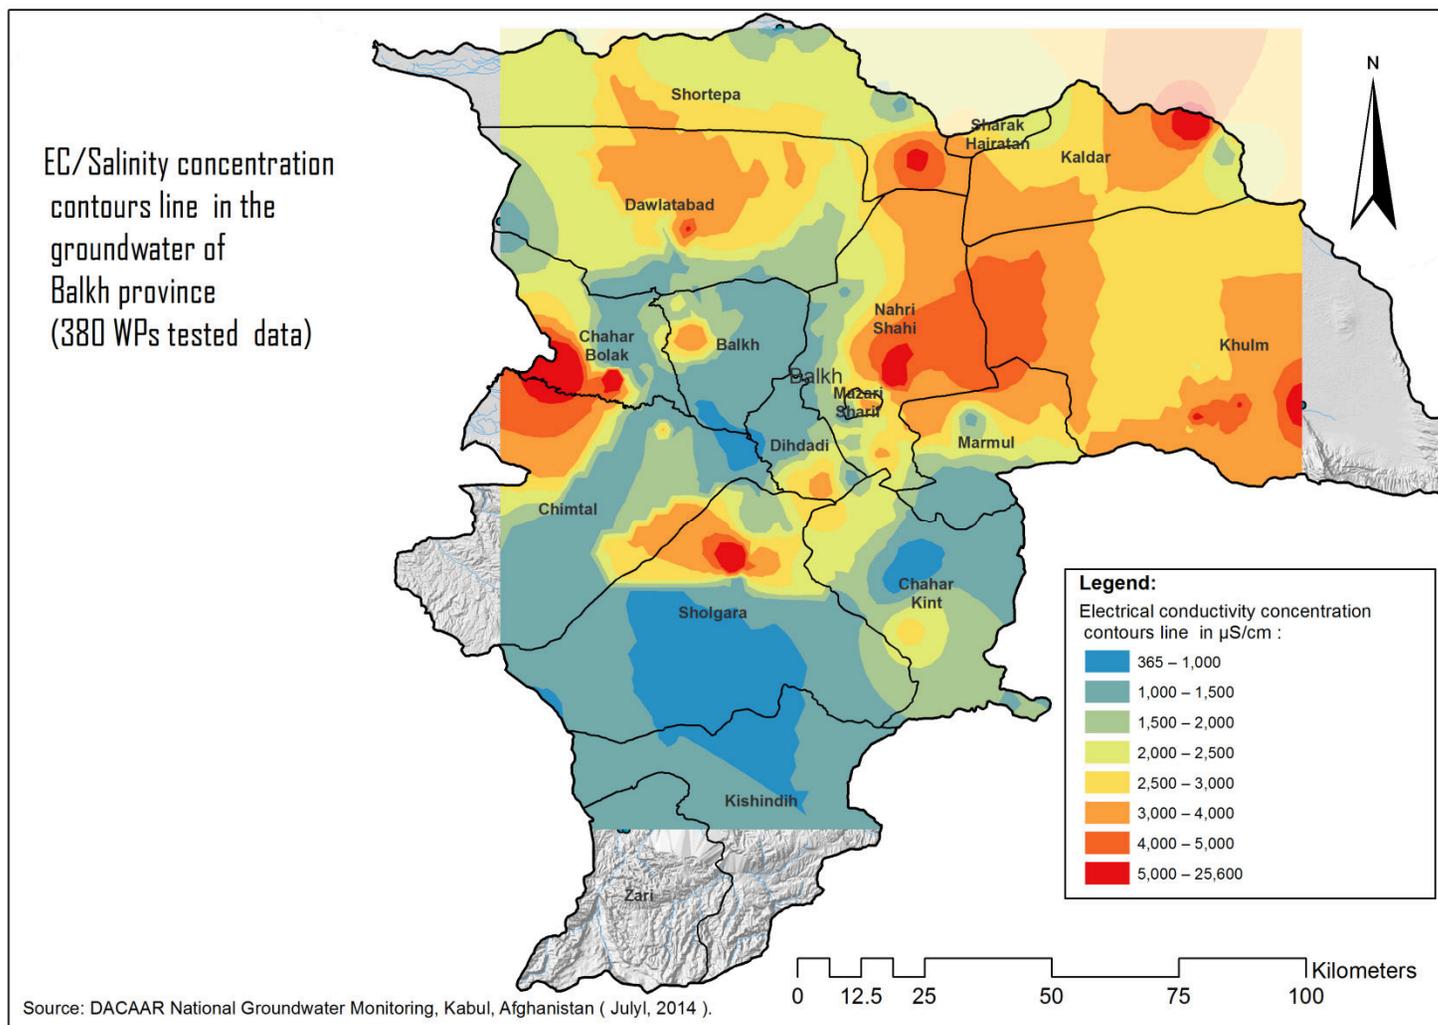

Annex 4 Contour lines fluoride - groundwater - Balkh Province

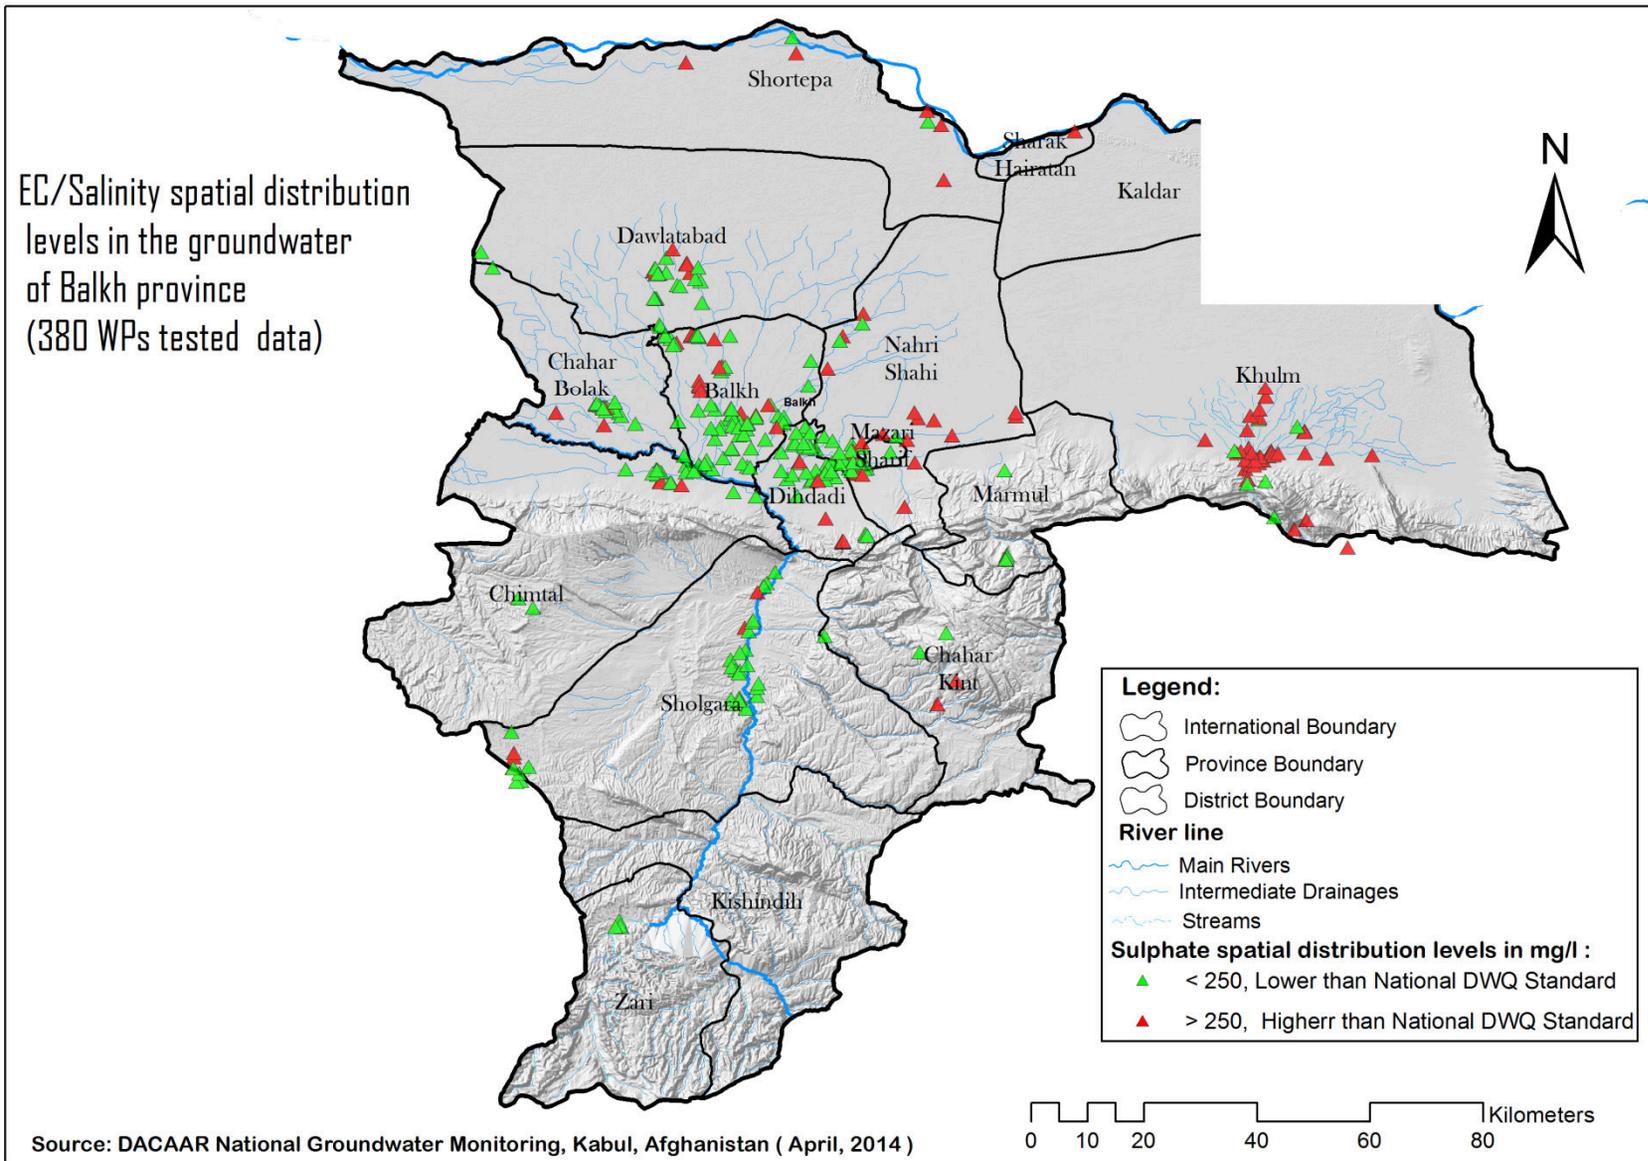

Annex 5 EC/Salinity distribution in Balkh Province

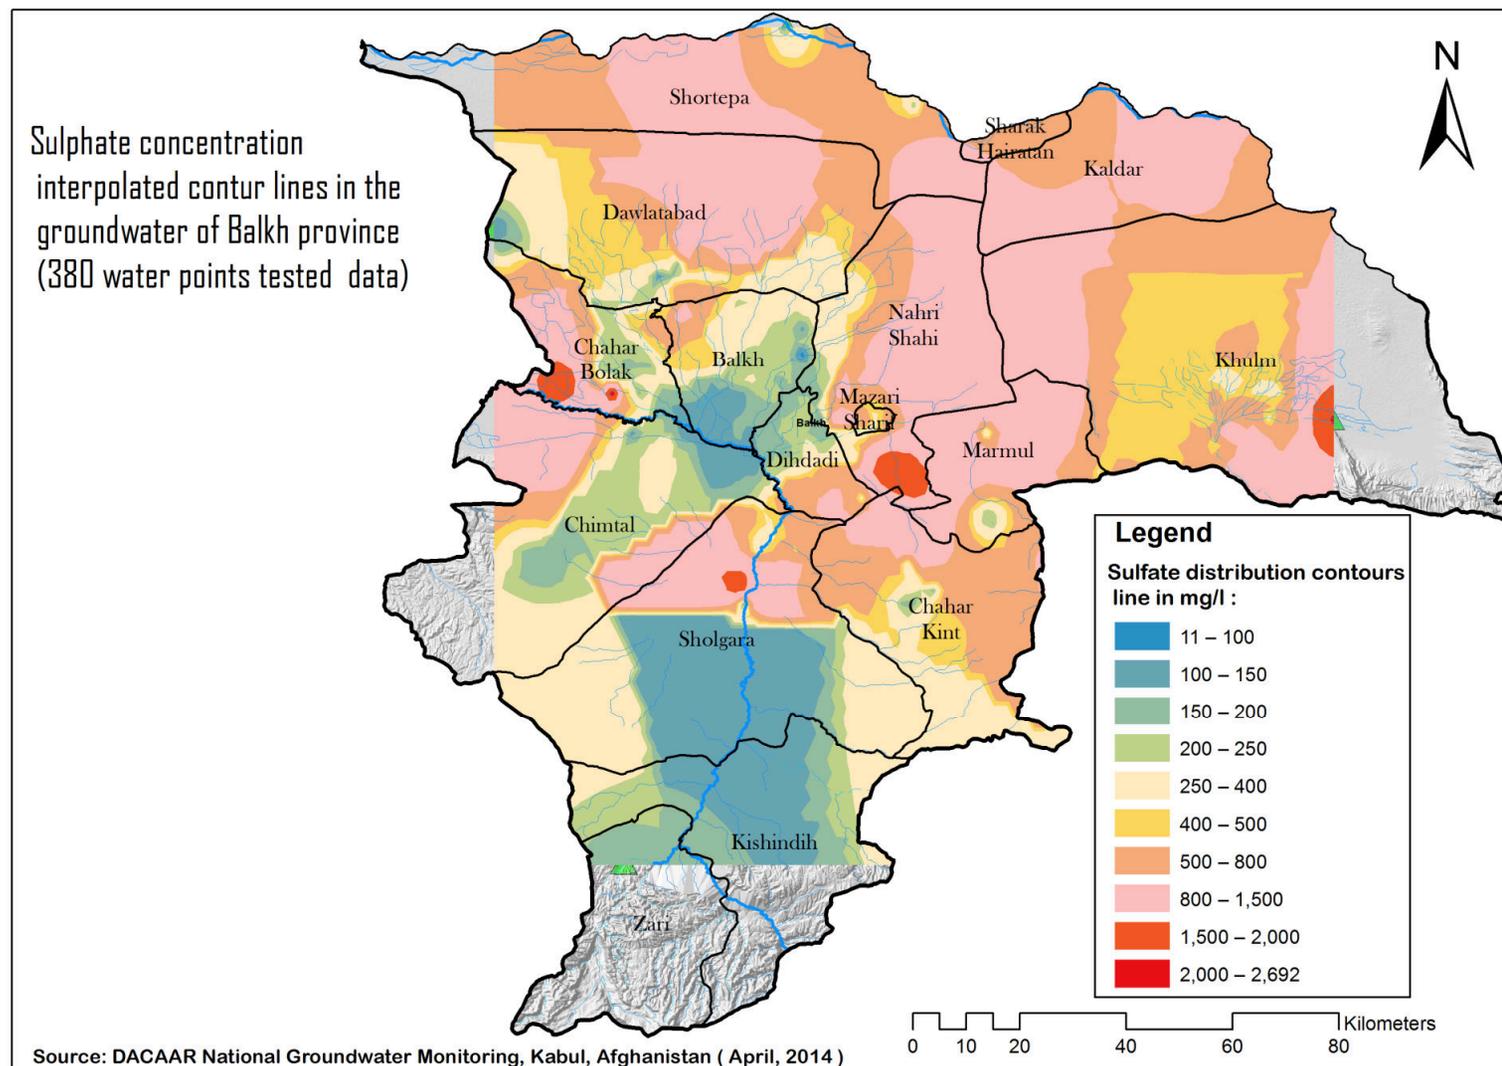

Annex 6 EC/ Salinity interpolated contour lines Balkh Province

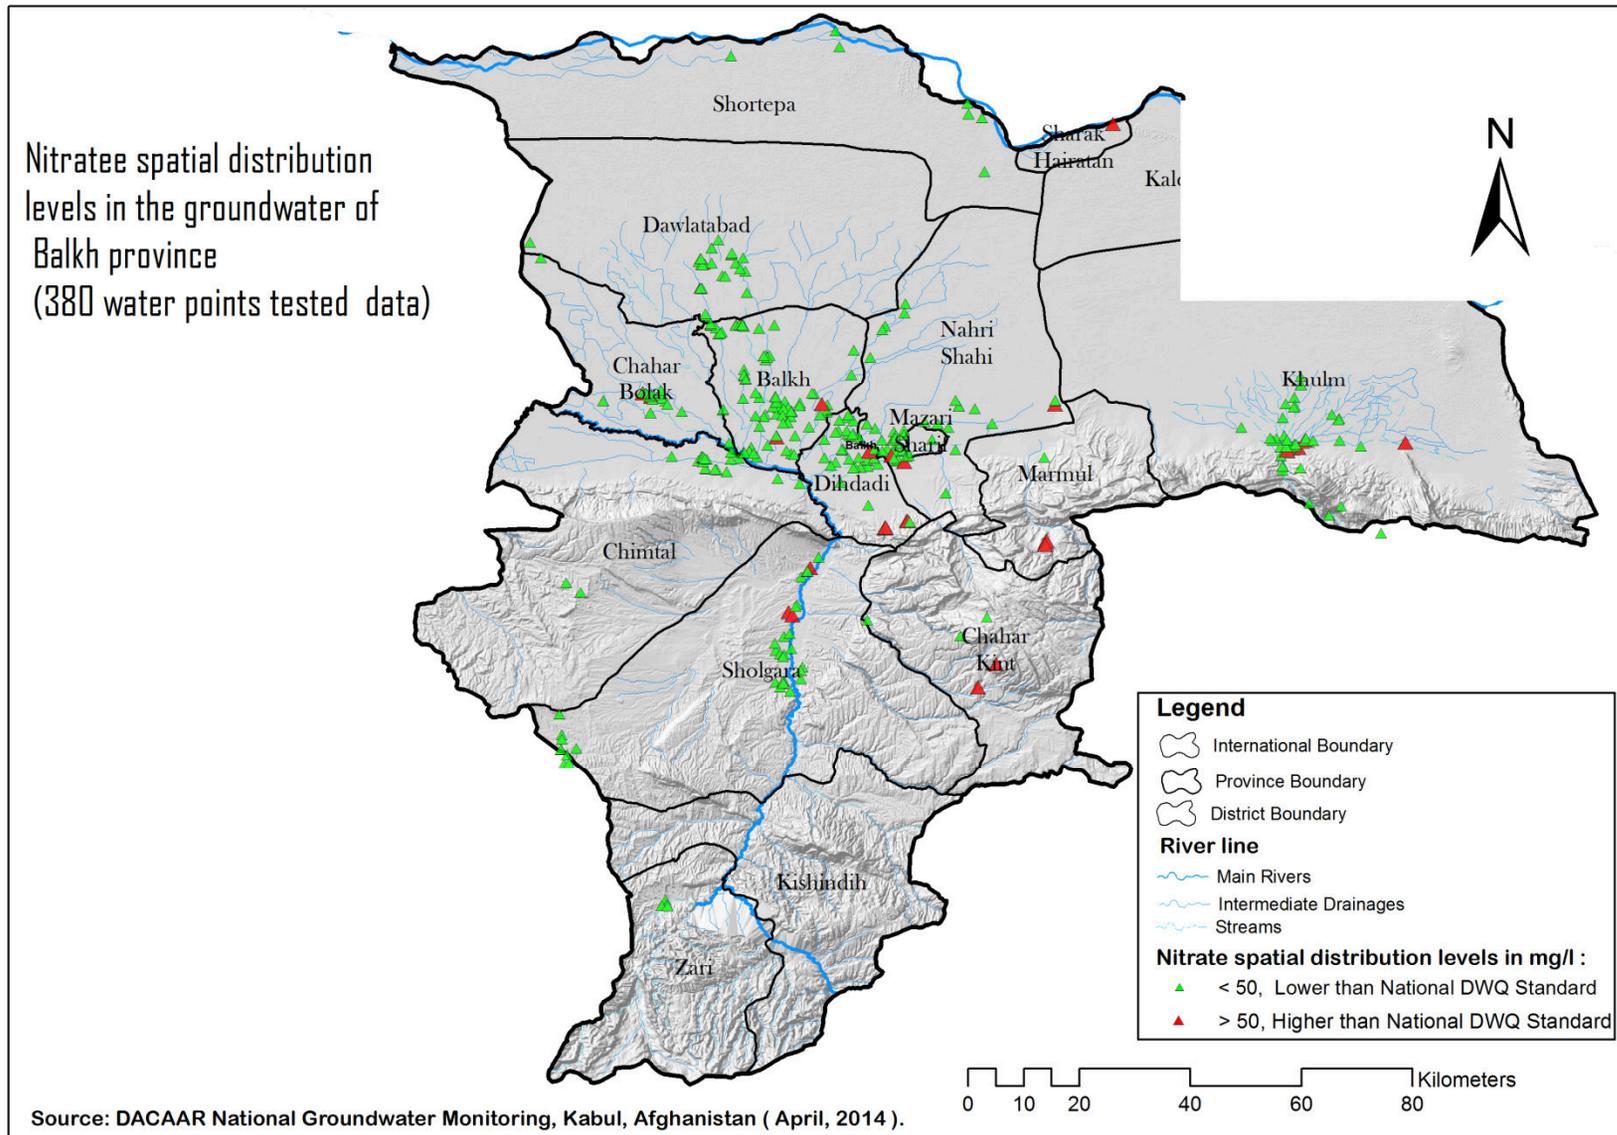

Annex 7 Sulphate occurrence in Balkh Province groundwater

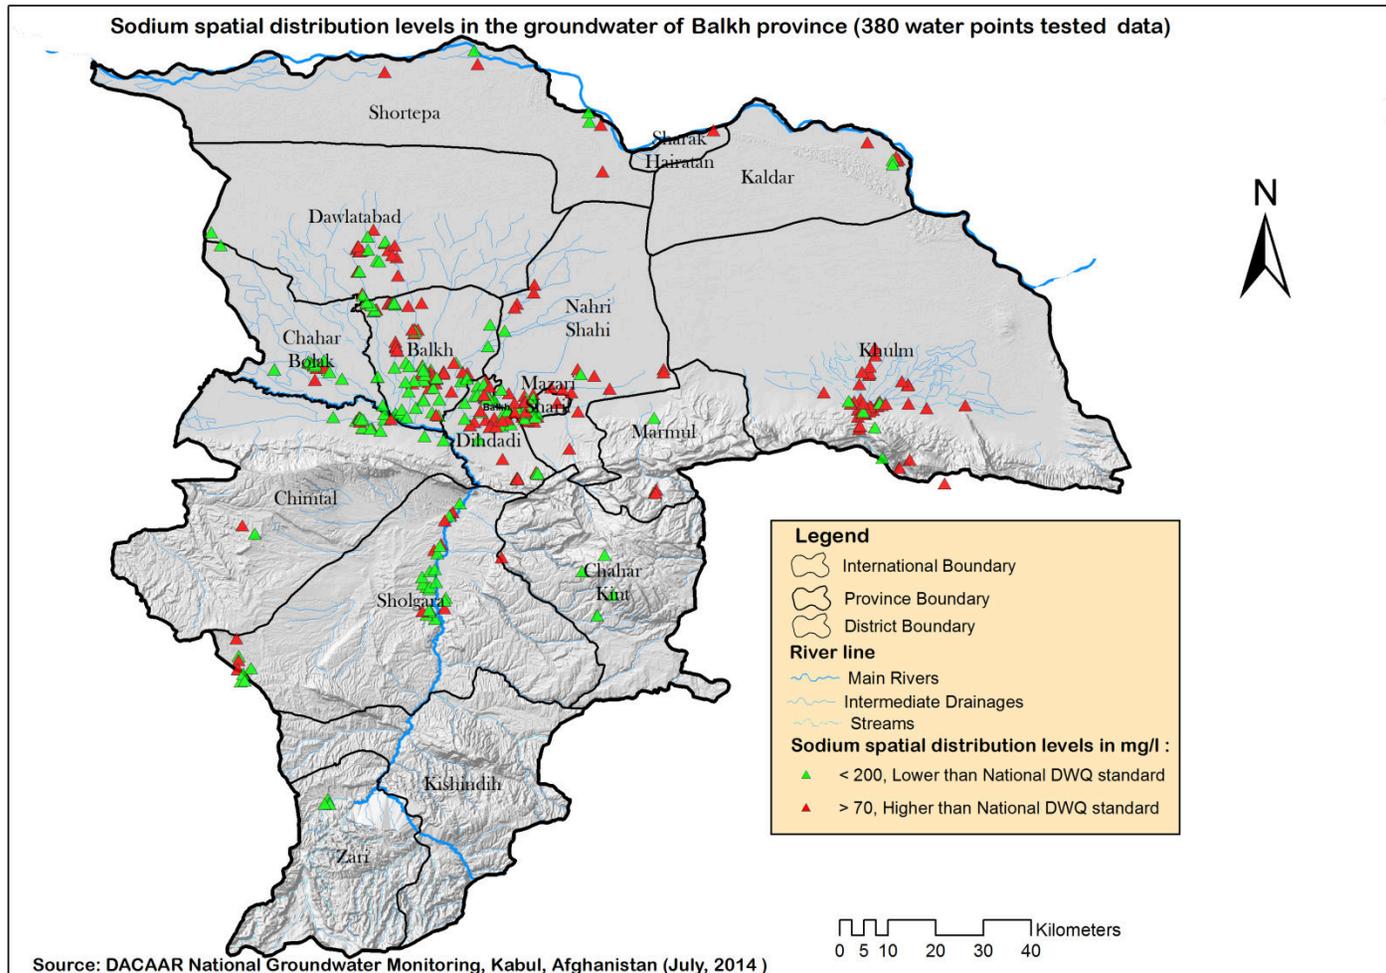

Annex 8 Sulphate interpolated contour lines in groundwater Balkh Province

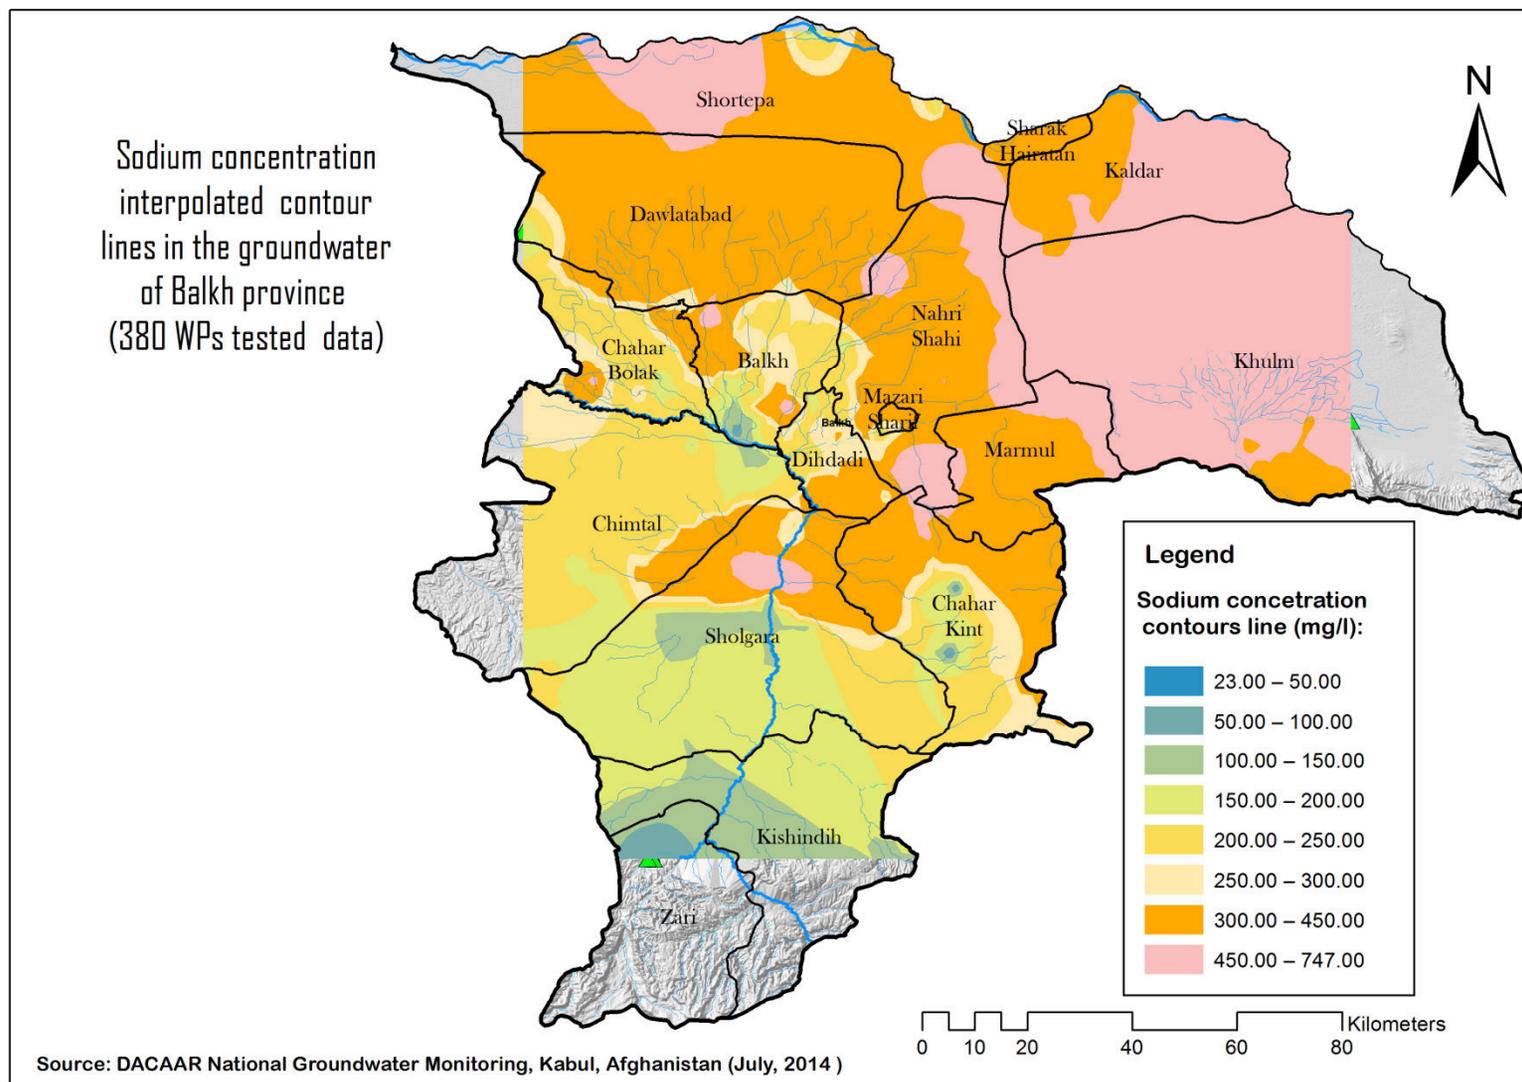

Annex 9 Nitrate levels in groundwater in Balkh Province

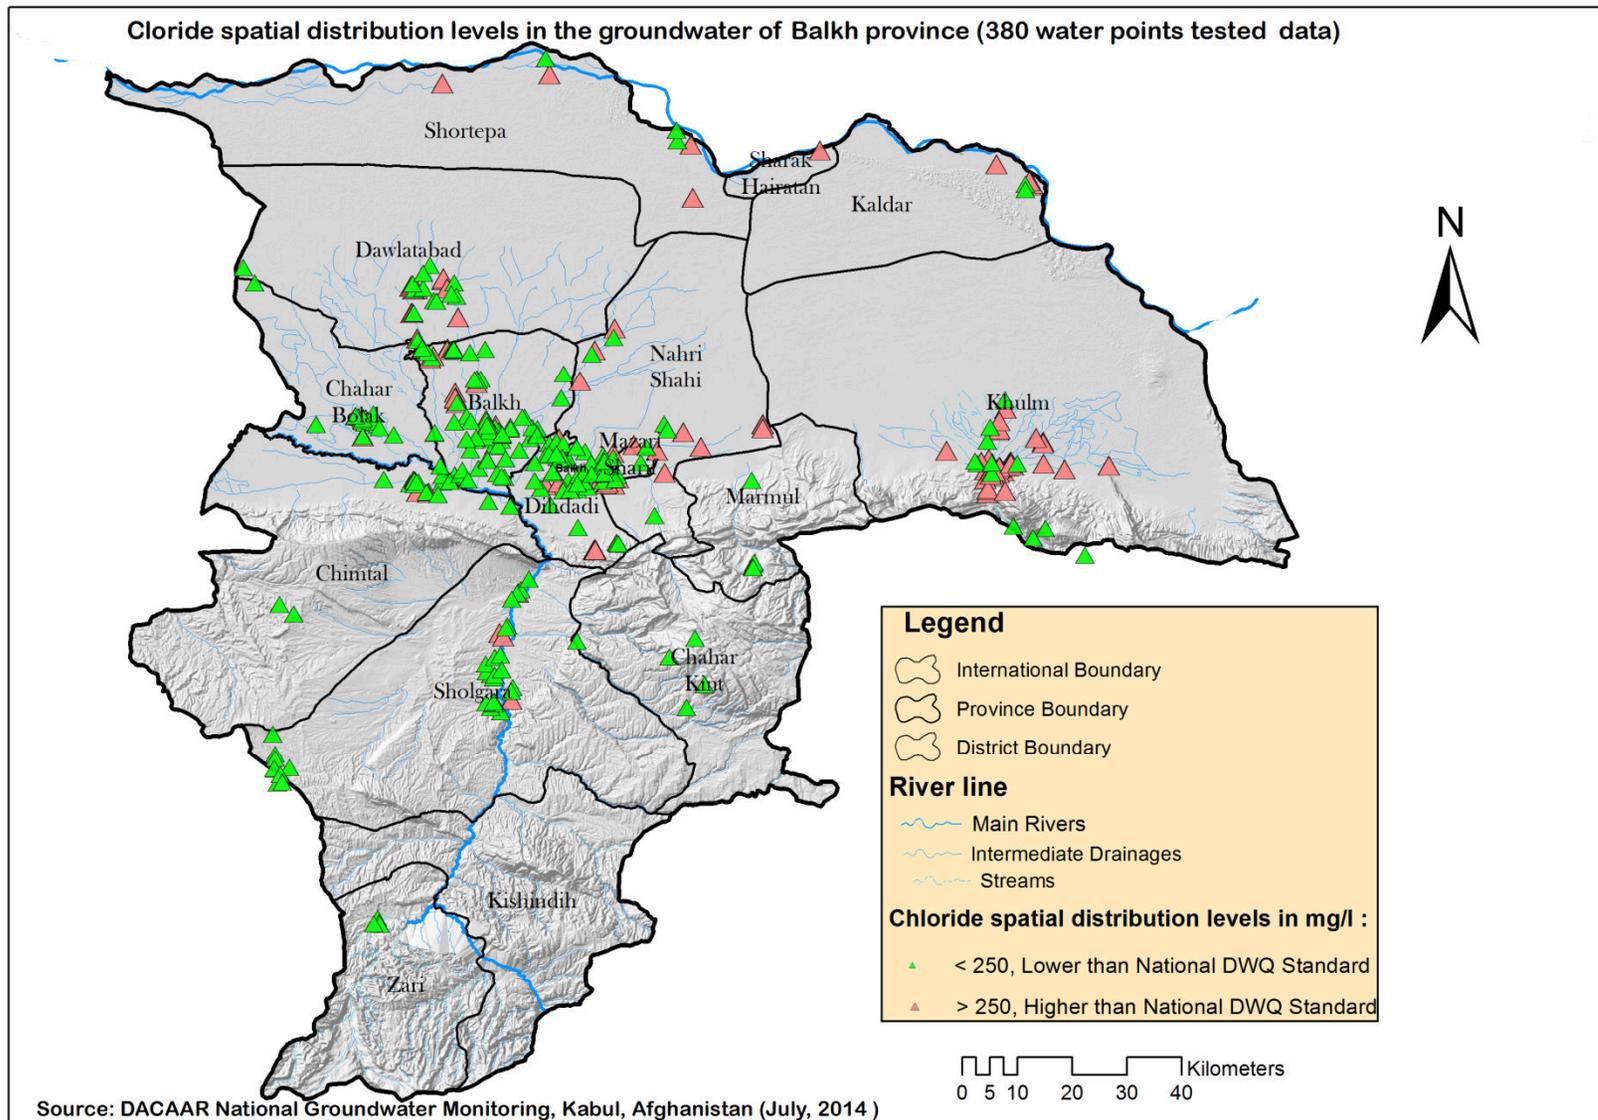

Annex 10 Sodium level in groundwater in Balkh Province

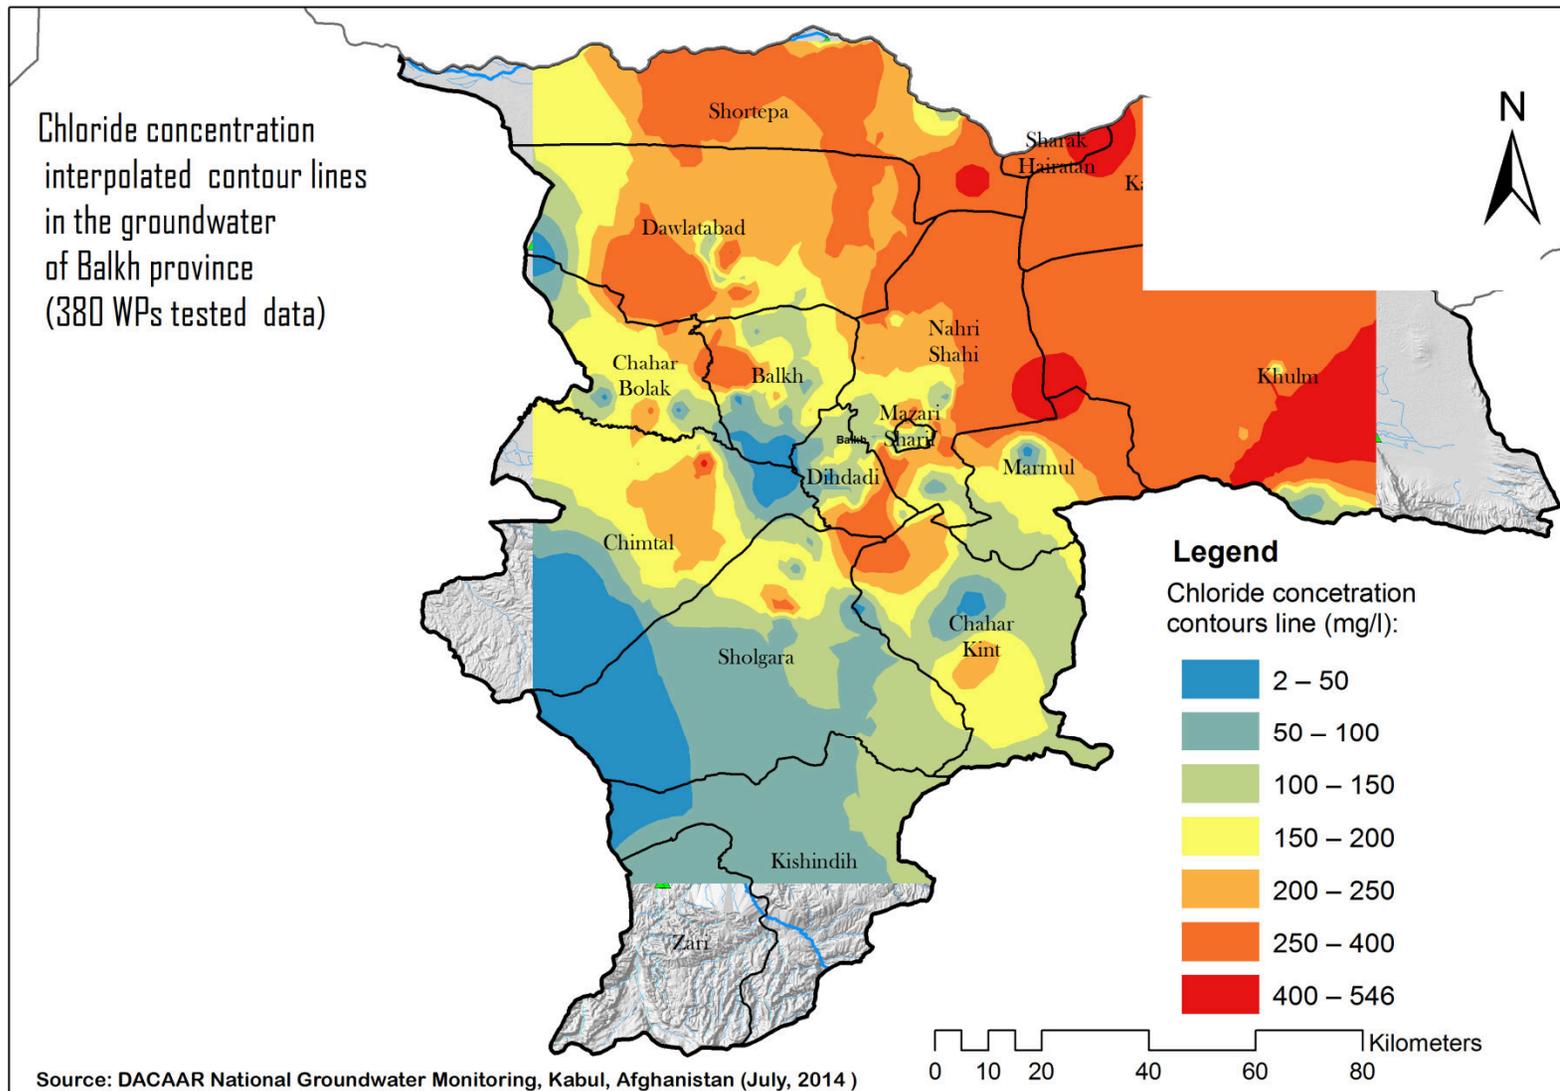

Annex 11 Sodium interpolated contour lines groundwater in Balkh Province

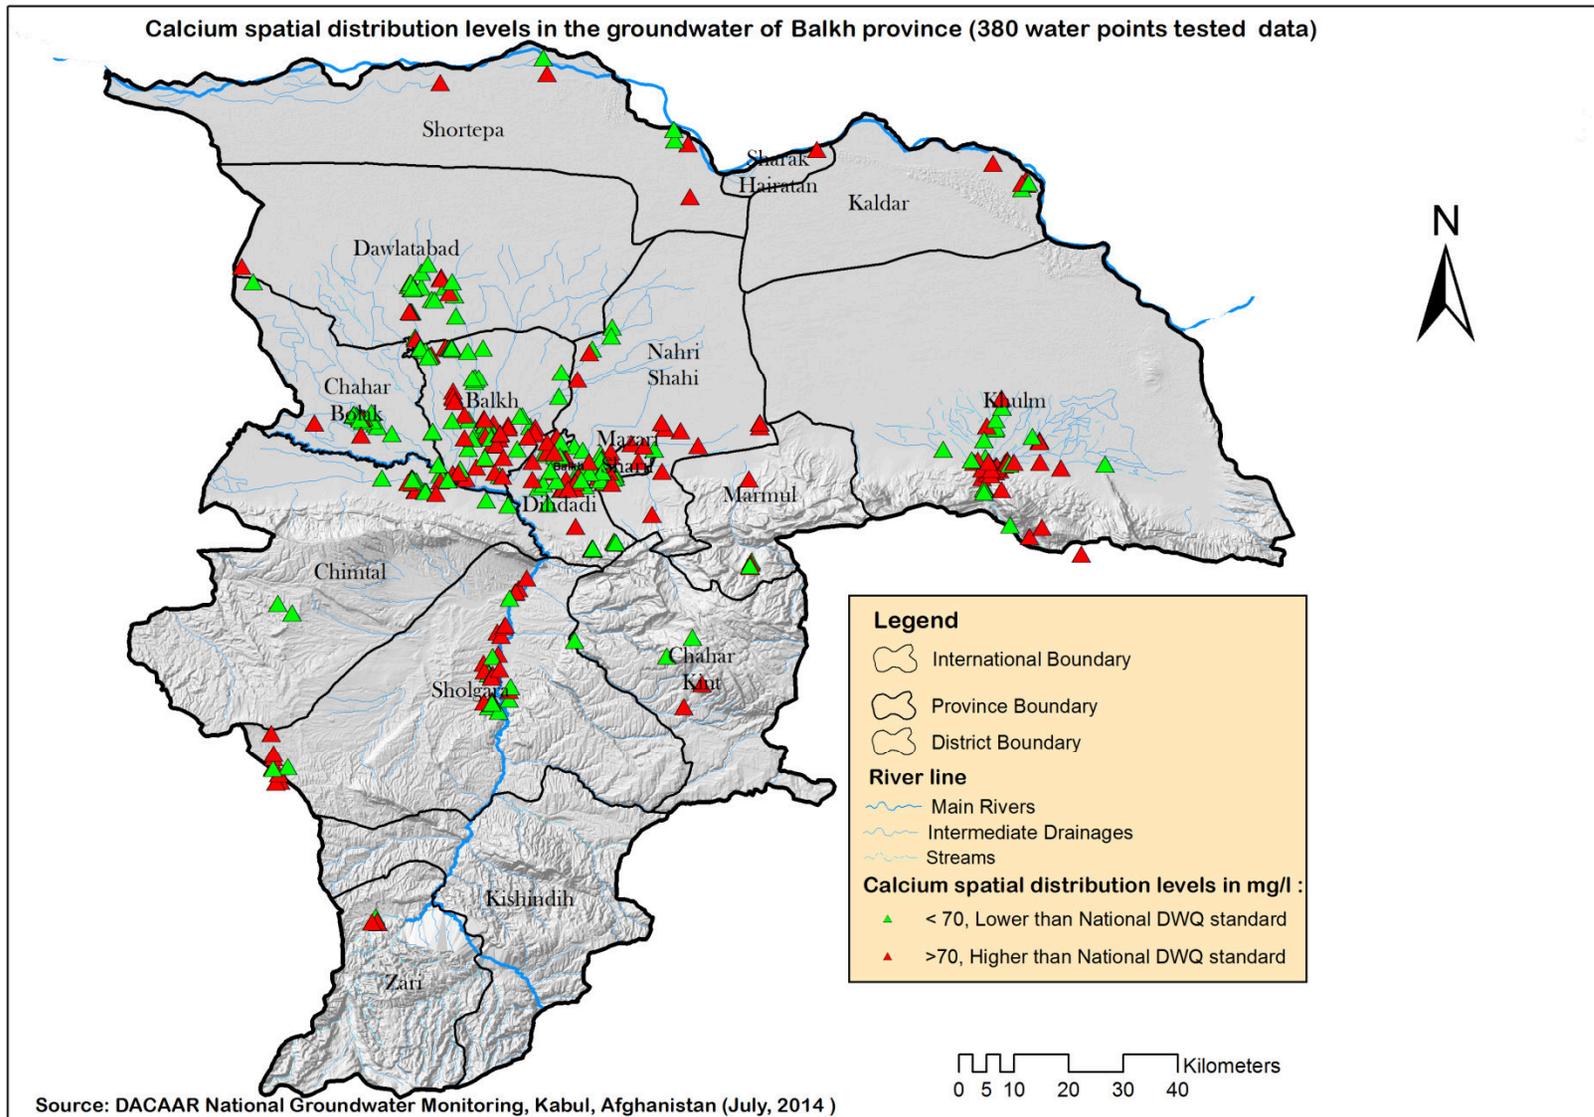

Annex 12 Chloride levels in groundwater in Balkh Province

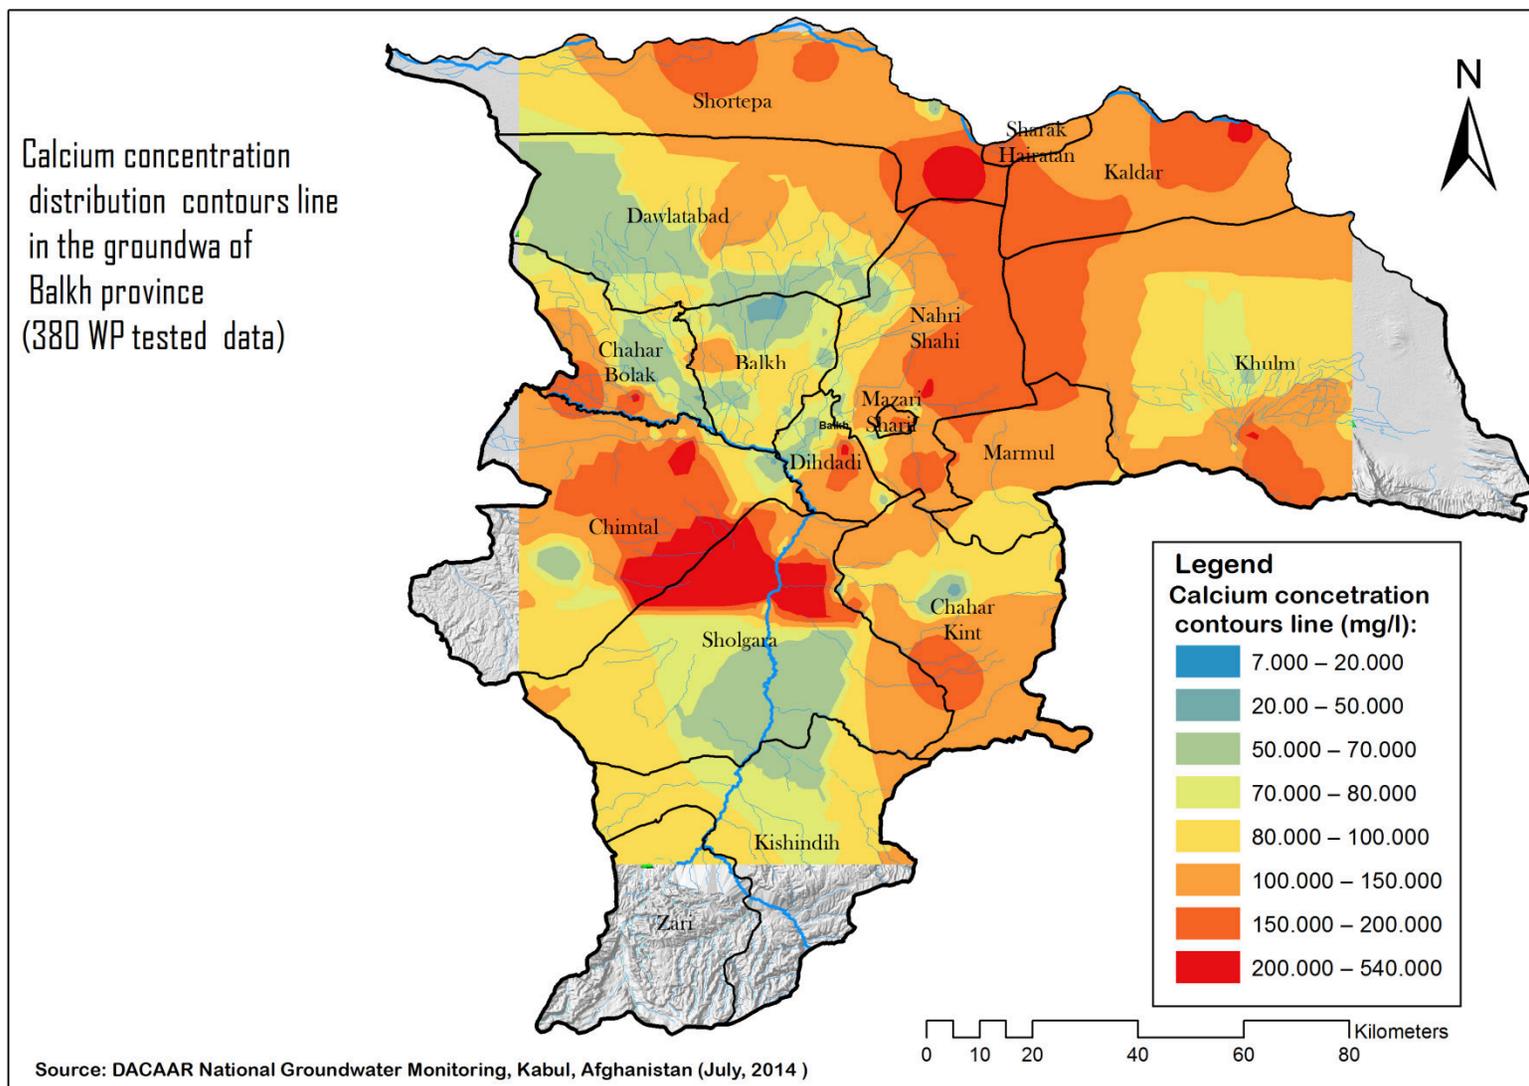

Annex 13 Chloride interpolated contour lines in groundwater Balkh Province

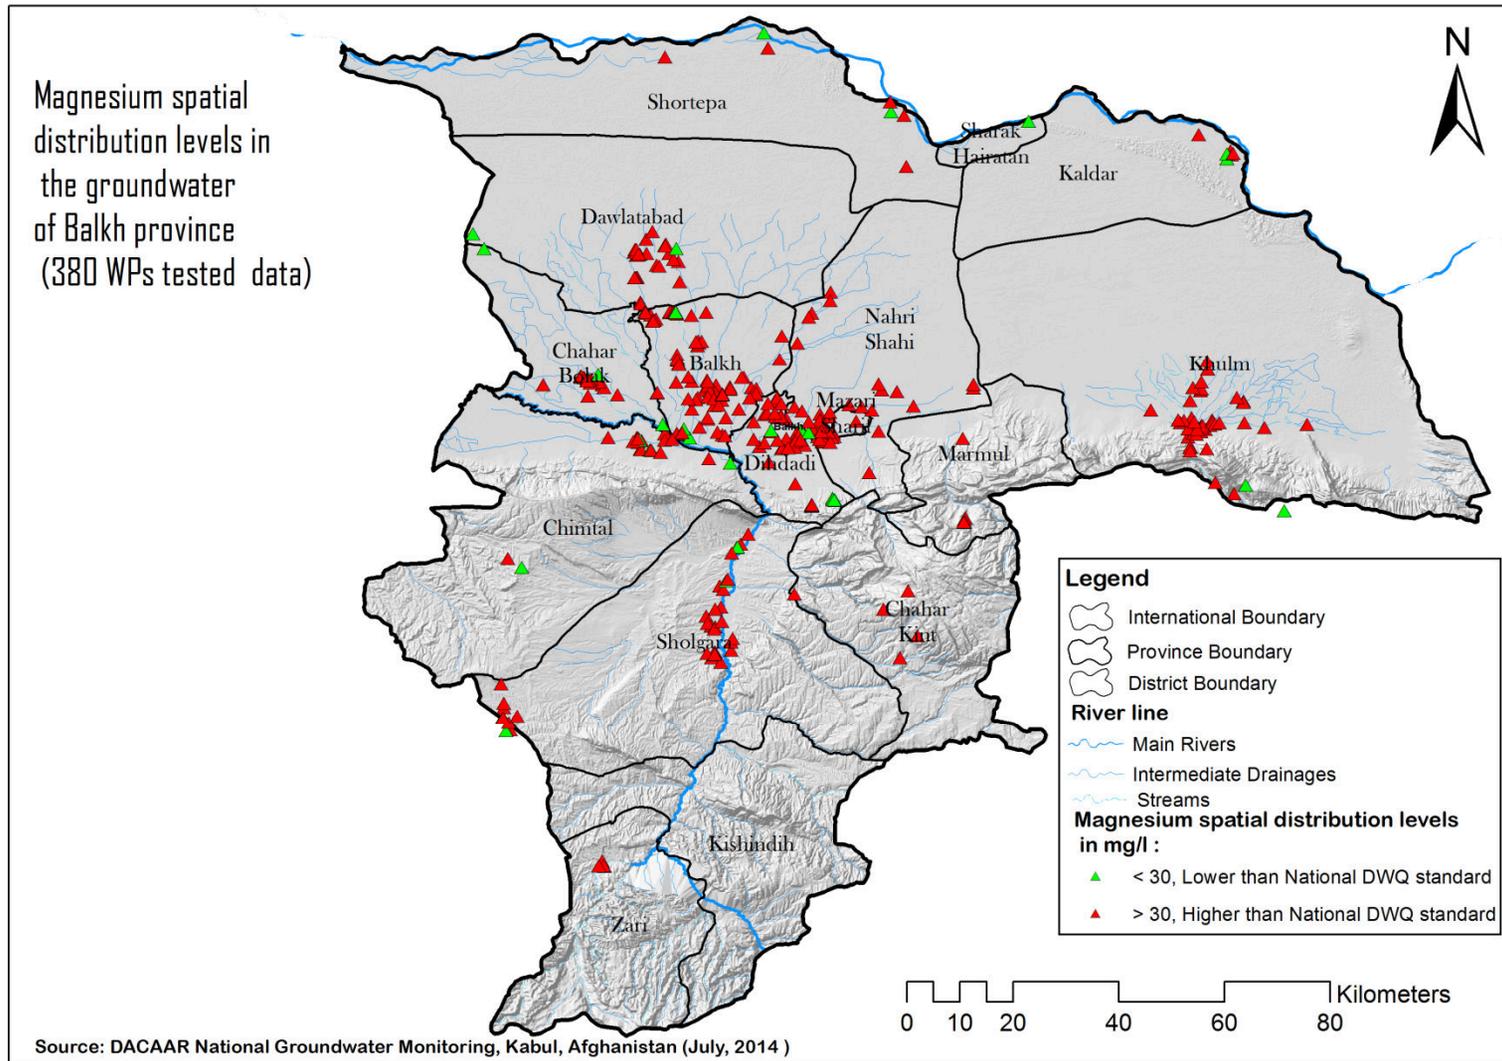

Annex14 Calcium levels in groundwater Balkh Province

Annex 15 Calcium interpolated contour lines in Balkh Province

Annex 16 Magnesium levels in groundwater in Balkh Province

Annex 17 Magnesium interpolated contour lines in groundwater Balkh Province
